The proposed action would result in increased shipping traffic and may increase potential vessel strikes to green turtles within the marine analysis area. Boat collisions are listed as a major problem for green turtle recovery off the continental U.S. Pacific Coast (NMFS 1998b). Sea turtles can be injured or killed when struck by a boat, especially by an engaged propeller. Eighty percent of sea turtle deaths reported recently in San Diego Bay and Mission Bay, California were associated with evidence of boat collision. Experiments conducted with a small 20-foot aluminum boat used to approach green sea turtles at various speeds found that turtles could avoid collision more effectively with vessels travelling at slow speeds (4 kilometers/hour) compared to vessels travelling at moderate and fast speeds (11 and 19 kilometers/hour, respectively; Hazel et al. 2007). However, methods for reducing boat collisions are not included in recovery objectives, and based on their warm water requirements, green sea turtles are likely to only be occasional visitors to waters as far north as Oregon.

The proposed action is expected to increase traffic by 240 additional ship transits through the marine analysis area each year of operation (inbound and outbound transits by 120 LNG carriers). Given the low population and occurrence of the green turtles in Oregon coastal waters and current estimate of vessel traffic, the addition of 240 LNG carrier transits through the marine analysis area is not expected to result in measurable additional ship strike-related mortality or injury to green turtles.

Underwater Noise

Green sea turtle hearing is most sensitive between 200 and 700 Hz (Bartol and Ketten 2006 cited in NSF 2011), which is within the same range of low frequencies generated by ships and sounds generated by large baleen whales (Würsig and Richardson 2009). However, most research has been related to sea turtles's responses to seismic noises while their resonses to ship noise have not been studied or documented.

Ambient noise in the northeast Pacific Ocean has increased over the past several decades. Comparisons of ambient noise from the 1990s with noise measurements taken during the 1960s indicate ambient noise has increased by about 10 dB (Andrew et al. 2002) although analyses of more recent vessel-traffic related noise is that such levels along the US west coast are holding steady or increasing slightly off Southern California but decreasing in the area off Oregon and Washington, Andrew et al. 2011).

Existing commercial vessels within the marine analysis area produce underwater noise levels that are comparable or exceed noise from the LNG tanker described by Hatch et al. (2008). Noise generated by various types of commercial ships (container ships, crude oil tankers, product tankers, bulk carriers, and others) were recently evaluated by McKenna et al. (2012). Underwater noise levels varied by ship type and also by vessel length, gross tonnage, vessel speed, and to some extent, vessel age (older vessels tended to be louder than newer vessels). Potential effects by LNG tanker-related noise on green sea turtles are remotely possible in the marine analysis area but any such noise would be commensurate with existing noise levels and would not be expected to cause injury or any measurable effect to any green sea turtles.

Fuel Spills

Fuel or lubricants spilled from LNG carriers at sea, or released during normal operations such as bilge tank flushing, could adversely affect green turtles directly if ingested or if turtles become coated in oil. Effects of oil on turtles include direct mortality due to oiling in hatchlings, juveniles, and adults, and negative impacts to the skin, blood, digestive and immune systems, and salt glands (Milton et al. 2010). Effects of potential spills from LNG carriers are not comparable to spills from oil tankers because LNG carriers only carry quantities of oil used for propulsion fuel and not the quantities transported by oil tankers.

The Federal Water Pollution Control Act, as amended by the CWA (33 U.S.C. 1251–1387), prohibits the discharge of oil upon the navigable waters of the U.S., which include, and, where it can be determined that the natural resources of the United States are impacted, out to the EEZ (200 miles). LNG carriers calling on the LNG Terminal would be required by the Coast Guard to have a vessel response plan in order to be adequately prepared for accidental spills, and comply with the U.S. and International regulations discussed under the blue whales section that prohibit the release of oil at sea. Green turtle forage areas exist outside of the marine analysis area in bays and inlets along the coast of Baja California, Mexico, and southern California (NMFS and FWS 1998a). Additionally, there are no known sea turtle nesting sites on the continental U.S. Pacific Coast. As green turtles are likely infrequent, transient visitors to the marine analysis area and the Oregon coast, adverse effects of fuel and lubricants spilled from 120 LNG carriers transiting the marine analysis area annually are expected to be insignificant and discountable, especially given the required spill prevention measures.

Cumulative Effects

The vessels transiting to and from the LNG Terminal would contribute to the ambient noise levels in the marine analysis area. However, the contribution of additional noise will occur within a context of diminishing traffic-related noise (Andrews et al, 2011), so the cumulative impact should be limited. Annual commercial ship traffic into and out of the Oregon International Port of Coos Bay has declined in recent years from a high of 310 deep-draft vessel calls at the Port in 1988 to 52 in 2016. The Port is also visited, by conservative estimates, by 50 tug/barge units per year, with 14 tug/barge units requesting pilotage during 2016 as per data from the Coos Bay Pilots Association (Whipple 2017). Even with the addition of 120 LNG carriers per year visiting the LNG Terminal, commercial ship traffic into Coos Bay would likely not reach historic levels.

As a result of this projected increase in vessel traffic, threats from ship strikes, underwater noise, and the effects of fuel spills are likely to increase. However, as green turtles are infrequent, transient visitors to the marine analysis area and the Oregon coast, cumulative effects from 120 LNG carriers transiting the marine analysis area combined with reasonably foreseeable non-federal projects are expected to be insignificant and discountable.

3.4.1.4 Conservation Measures

Measures to reduce ship speeds once inside the Coos Bay navigation channel to between 4 to 6 knots and within the marine analysis area when pods or large assemblages of cetaceans are observed near an underway ship would provide some protection to green turtles. However, it is highly unlikely that green turtles or other sea turtles would be seen from an LNG carrier. Nevertheless, the same *Ship-Strike Reduction Plan*, including marine mammal avoidance guidelines that were described in section 3.2.1.4 (Blue Whale), applies to green turtles further reducing any potential impacts in the unlikely event that a green turtle is found in the analysis area.

3.4.1.5 Determination of Effects

Species

The Project **may affect** green turtles because:

- green turtles may occur within the marine analysis area during operation of the proposed action; and
- the proposed action would increase shipping traffic (LNG carriers) within the marine analysis area.

However, the Project is **not likely to adversely affect** green turtles because:

- the increase in annual ship traffic due to the proposed action is expected to cause an immeasurable increase for potential ship strikes to green turtles;
- JCEP would provide a Ship Strike Avoidance Measures Package to shippers calling on the LNG Terminal that consists of multiple measures to avoid striking marine mammals, which should also benefit sea turtles;
- LNG carriers approaching Coos Bay would be traveling slowly and be escorted by tractor tugs from 5 nmi offshore to the LNG Terminal;
- noise produced by LNG carriers would contribute to overall noise within the marine analysis area en route to Coos Bay and increased ship noise could affect green sea turtle behavior. However, JCEP expects that the noise levels of the LNG carriers would be comparable to the noise levels of existing ship traffic and would be infrequent enough so as not to cause injury or result in behavioral changes.

3.4.2 Leatherback Turtle

3.4.2.1 Species Account and Critical Habitat

Status

Leatherback turtles were listed as endangered under the Endangered Species Conservation Act on December 2, 1970 (FWS 1970) and have been listed under the ESA since its implementation in 1973. NMFS (2017e) recognizes two subpopulations of Pacific leatherback turtles, Eastern and Western. Eastern Pacific leatherbacks nest along the Pacific coast of the Americas in Mexico and Costa Rica while Western Pacific leatherbacks nest in the Indo-Pacific and migrate back to feeding areas off the Pacific coast of North America including the coast of Oregon (NMFS 2017e).

Threats

The NMFS and FWS (1998b) cited 22 general threats to leatherbacks; egg collection and bycatch in fishing gear are the primary reasons for the declines in Pacific leatherback turtle populations.

Direct threats to leatherback turtles include harvesting. The primary threat to leatherback turtles on the continental U.S. Pacific Coast continues to be incidental take in commercial fisheries operations (NMFS and FWS 1998b). Other threats include ingestion of debris, primarily plastics and plastic bags that are thought to be mistaken for jellyfish and eaten, leading to esophagus and stomach blockage and eventually death (Mrosovsky et al. 2009; Plotkin 1995). These deaths, and the evidence for this type of death by this specific type of ingestion, appear to be on the rise (Schuyler, et al. 2013). Threats at nesting grounds outside the United States still remain from collection of eggs and development along coastal areas. In addition, artificial light (during egg hatch viewing) causes confusion of newly hatched turtles that head in the direction of the light rather than out to sea (Plotkin 1995; FWS 2012e; NMFS and FWS 1998b).

Species Recovery

NMFS issued a recovery plan for the U.S. Pacific Coast population on May 22, 1998. The recovery goal (NMFS and FWS 1998b) is to delist the species, and the plan listed the following necessary actions:

- Eliminate incidental take of leatherbacks in United States and international commercial fisheries.
- Support the efforts of Mexico and the countries of Central America to census and protect nesting leatherbacks, their eggs, and nesting beaches.
- Determine movement patterns, habitat needs, and primary foraging areas for the species throughout its range.
- Determine population size and status in U.S. waters through regular aerial or on-water surveys.
- Identify stock home ranges using DNA analysis.

The stepdown outline in the recovery plan included the following recommendations:

- Protect and manage turtles on nesting beaches.
- Protect and manage nesting habitat.
- Protect and manage leatherback turtle populations in the marine habitat.
- Protect and manage marine habitat, including foraging habitats.
- Support existing international agreements and conventions to ensure that turtles in all life-stages are protected in foreign waters.
- Encourage ratification of CITES for all non-member Pacific countries, compliance with CITES requirements, and removal of sea turtle trade reservations held by member nations.

- Develop new international agreements to ensure that turtles in all life-stages are protected in foreign waters.
- Develop or continue to support informational displays in airports that provide connecting legs for travelers to the areas where leatherbacks occur.

Life History, Habitat Requirements, and Distribution

The leatherback is the largest, most migratory, and widest ranging of all extant sea turtles (NMFS 2017e). Leatherback sea turtle nesting grounds are located around the world, with the largest remaining nesting assemblages found on the coasts of northern South America and West Africa. Adult leatherback sea turtles are capable of tolerating a wide range of water temperatures, and have been sighted as far north as the Gulf of Alaska (NMFS and FWS 2007a). Their diet consists of soft-bodied prey, such as jellyfish and tunicates. Nesting occurs on sandy tropical beaches, with each female laying several clutches at intervals of 8 to 12 days. Mating occurs in the waters adjacent to nesting beaches within migration corridors. After nesting, female leatherbacks migrate from tropical waters to more temperate latitudes, which support high densities of jellyfish prey in the summer (NMFS and FWS 1998b). Incubation of eggs takes between 55 and 75 days, and hatching occurs at night. Sexual maturity is reached between 6 and 10 years (FWS 2012e). No known nesting locations occur on the U.S. Pacific Coast.

NMFS (2012d) defined nine geographic areas along the continental U.S. Pacific Coast from Washington to Northern California that are occupied by leatherback turtles. Areas 2 and 3 include nearshore waters from Point Arena in northern California to Cape Flattery in Washington, extending offshore to the 2,000-meter isobath. Area 2 (Cape Blanco to Cape Flattery) includes most of the Oregon coast and is a principal foraging area for leatherbacks. They feed on a variety of moon jellies and brown sea nettles that are present in high densities associated with the Columbia River Plume and Heceta Bank, Oregon (NMFS 2012d). Areas 4 and 5 extend offshore west of Areas 2 and 3 to the EEZ. Jellyfish densities in those areas are unknown and likely serve as secondary foraging areas and areas of passage to the primary foraging region in Area 2. The marine analysis area is located within Area 2.

Population Status

In recent decades, Western Pacific leatherbacks have declined more than 80 percent (NMFS 2017e). Turtles foraging along the California coast are part of the Western Pacific subpopulation (Harris et al. 2011), and the same is assumed for leatherbacks foraging along the Oregon and Washington coasts. Between 1984 and 2011, there was an overall significant decline of 78 percent in the number of leatherback turtle nests monitored in Papua Barat, Indonesia (Tapilatu et al. 2013). Approximately 75 percent of the leatherbacks nesting in the western Pacific nest at Papua Barat. In the Pacific, the International Union for Conservation of Nature estimated that leatherback turtle populations have declined by 80 percent over three generations (Wallace et al. 2013).

Critical Habitat

Critical habitat was established for the Atlantic population in the U.S. Virgin Islands on March 23, 1979 (NMFS 1979). NMFS designated critical habitat for the Pacific population in 2012 (77 Fed. Reg. 4170), designating approximately 16,910 square miles as critical habitat for leatherback turtles along the California coast from Point Arena to Point Arguello and 25,004 square miles along the Washington and Oregon coasts from Cape Blanco, Oregon to Cape Flattery, Washington (NMFS 2012d).

NMFS (NMFS 2012d) originally identified two primary constituent elements (PCEs) to determine areas proposed as critical habitat for the Pacific population of leatherbacks; 1) occurrence of prey species, primarily jellyfish, of sufficient condition, distribution, diversity, and abundance to support individual as well as population growth, reproduction and development, and 2) migratory pathway conditions to allow for safe and timely passage and access to/from/within high use foraging areas. However, NMFS subsequently eliminated the second PCE, an identified migratory pathway. In the final designation, there is only one PCE, occurrence of prey species, primarily scyphomedusae of the order Semaeostomeae (especially brown sea nettles, *Chrysaora fuscescens*) of sufficient condition, distribution, diversity, abundance and density necessary to support individual as well as population growth, reproduction, and development of leatherbacks.

3.4.2.2 Environmental Baseline

Analysis Area

The analysis area applicable to leatherback turtles is the area directly off Coos Bay out to the continental shelf break, which is represented as a depth of 200 meters, the same as the marine analysis area described above for green turtles and blue whales (see figure 2.1.1-2).

Species Presence

The leatherback sea turtle is the most common sea turtle in U.S. waters north of Mexico (NMFS and FWS 1998b). Leatherbacks occur as far north as Alaska, and numerous sightings have been documented off the Oregon coast. Green et al. (1992) observed 16 Pacific leatherback turtles off the Oregon and Washington coasts, all of them north of a point due west of Pacific City in Tillamook County, Oregon. Sixty-two percent of the sightings occurred over the continental slope, with the remainder occurring over the continental shelf. Incidental catch of leatherback turtles has also occurred in gill-nets off the coasts of Washington, Oregon, and California. Of 104 records of sea turtle strandings on the continental U.S. Pacific Coast between 1982 and 1991, 50 were leatherbacks (NMFS and FWS 1998b). No attempt has yet been made to assess the status of foraging populations. Despite occasional reports of leatherbacks sighted at sea, and a growing database documenting their incidental catch in coastal and pelagic fisheries, there are very few areas where the species is routinely encountered. An exceptions is Monterey Bay, California (NMFS and FWS 1998b). These data suggest that leatherback sea turtles would be present in the marine analysis area in higher densities relative to other sea turtle species, but still in low densities overall.

Habitat

Adult leatherback turtles are highly migratory and available information indicates that eastern Pacific migratory corridors exist along the U.S. Pacific Coast (NMFS and FWS 1998b). The continental U.S. Pacific Coast may represent some of the most important foraging habitat in the world for the leatherback turtle (NMFS and FWS 1998b). Therefore, the marine analysis area is assumed to provide important habitat for leatherback turtles. Coastal upwelling of the California Current occurs along the Oregon Coast north of Cape Blanco. Peak numbers of leatherback turtles (July to September) occur in neritic zones when there are intermittent decreases in upwelling that allow surface water temperatures to increase to their warmest annual levels. Leatherback turtles aggregate in the warm, highly productive coastal areas to forage on their preferred prey, scyphomedusae, the cnidarian jellies (NMFS 2012d).

Critical Habitat

NMFS' final rule designated critical habitat within 25,004 square miles along the Washington and Oregon coasts from Cape Blanco, Oregon to Cape Flattery, Washington (NMFS 2012d). NMFS defined an area (Area 2) from Cape Blanco to Cape Flattery, including most of the Oregon coast, as a principal foraging area for leatherbacks. They feed on a variety of moon jellies and brown sea nettles that are present in high densities associated with the Columbia River Plume and Heceta Bank, Oregon. Based upon the best available scientific information, the features of Area 2 produce sufficient prey to provide forage for leatherback turtles that is essential to the conservation of the species, thus this area contains the prey PCE. Critical habitat extends to a water depth of 80 meters from the ocean surface and is delineated along the shoreline at the line of extreme low water offshore to the 2,000-meter depth contour. Critical habitat includes nearshore waters through which LNG carriers would transit to Coos Bay and the LNG Terminal.

3.4.2.3 Effects of the Proposed Action

Direct and Indirect Effects

Direct effects of the proposed action include injury and/or mortality due to ship strikes, underwater ship noise, and potential adverse effects from fuel spills at sea. Spills could indirectly affect leatherback turtles by impacting forage species. These effects are addressed below.

Ship Strikes by LNG Carriers

Sea turtles can be injured or killed when struck by a boat, especially if struck by an engaged propeller (NMFS and FWS 1998b). The proposed action would result in increased shipping traffic and may increase potential vessel strikes to leatherback sea turtles within the marine analysis area. However, the largest threat to leatherback turtles outside of their nesting grounds is entanglement in gill-nets and other incidental take. While Harris et al. (2011) reports 2 of 19 leatherback turtles examined had multiple parallel lacerations in the carapaces that had healed and were consistent with wounds from boat propellers, boat collisions are not listed as a current threat to the recovery of leatherback populations (NMFS 2017e). Risk of collision increases with increased vessel speed (Hazel et al. 2007), as discussed for green sea turtles, above. The risk was described for small craft but is unknown for large tankers.

The proposed action is expected to increase traffic by 240 additional ship transits through the marine analysis area each year of operation (inbound and outbound transits by 120 LNG carriers). Due to the known occurrence of the leatherback turtles in Oregon coastal waters, the addition of 240 LNG carrier transits through the marine analysis area may result in additional ship strike-related mortality or injury to leatherback turtles. The paucity of documented ship-strike incidences to sea turtles in general or frequencies of collision precludes any quantification of effects to leatherback turtles of additional vessel traffic due to LNG carriers. However, although the proposed action could result in additional potential for ship strike-related mortality or injury, these incidents are still expected to be rare occurrences, and thus the effects on leatherback turtles are discountable.

Underwater Noise

Loggerhead sea turtle hearing is most sensitive to lower frequencies below 1000 Hz (Bartol et al. 1999; Martin et al. 2012, Dow Piniak et al. 2012), within the same range of low frequencies generated by ships and sounds generated by large baleen whales (Würsig and Richardson 2009). As with green sea turtles, the same hearing sensitivity is assumed to be the case for leatherback turtles, and the effects are expected to be similar. See section 3.4.1, Green Turtle, above for a full discussion of these effects. With the existing levels of background shipping noise and the expected increase in shipping traffic, effects by LNG carrier-related noise on leatherback sea turtles are possible in the marine analysis area but the noise would be commensurate with existing noise levels and would not be expected to cause injury or any measurable effect.

Fuel Spills

Fuel or lubricants spilled from LNG carriers at sea, or released during normal operations such as bilge tank flushing, could impact both leatherback turtles and their jellyfish prey. Known effects of oil on turtles include direct mortality due to oiling in hatchlings, juveniles, and adults, and negative impacts to the skin, blood, digestive and immune systems, and salt glands (Milton et al. 2010). As described in section 3.4.1.3 for green turtles, direct effects of potential spills from LNG carriers are not comparable to spills from oil tankers because LNG carriers only carry quantities of oil used for propulsion fuel and not the quantities transported by oil tankers. However, low-level exposure to oil may still affect sea turtles, although effects related to specific toxicity levels have not been determined (Milton et al. 2010).

NMFS (2012d) identified LNG projects and oil spills as activities that may affect leatherback turtle prey within Area 2, which coincides with the nearshore habitat that would be transited by Project LNG carriers. Fuel and oil spilled by LNG carriers has the potential to affect leatherback turtles by altering prey abundance and prey contamination levels. However, as discussed above under green turtles, LNG carriers calling on the LNG Terminal would be required to comply with U.S. and International regulations regarding spill prevention. As a result, LNG carriers are not likely to contribute oil, fuel, or lubricants to the marine analysis area to the extent that would adversely affect leatherbacks or their prey species.

Cumulative Effects

Annual commercial ship traffic into and out of the Oregon International Port of Coos Bay has declined in recent years from a high of 310 deep-draft vessel calls in 1988 to 52 in 2016. The Port is also visited, by conservative estimates, by 50 tug/barge units per year, with 14 tug/barge units requesting pilotage during 2016 as per data from the Coos Bay Pilots Association (Whipple 2017).. However, even with the addition of 120 LNG carriers per year visiting the LNG Terminal, commercial ship traffic into Coos Bay would likely not reach historic levels.

As a result of this projected increase in vessel traffic, threats from ship strikes, underwater noise, and the effects of fuel spills are likely to increase. However, as discussed in section 3.2.1 for blue whales, it appears that the background rate of oil spills off the Oregon coast by fishing vessels, recreation vessels, and other vessel types is generally low, a frequency that would be expected to continue into the foreseeable future. According to annual reports published by the

Pacific States/British Columbia Oil Spill Task Force between 2002 and 2007, ODEQ reported an average of 37 spills annually from fishing, recreational, and other vessels.

With their spill prevention measures, LNG carriers are not likely to contribute oil, fuel, or lubricants to the marine analysis area to the extent that would adversely affect leatherback prey species. Additionally, although an increased likelihood of ship strikes are possible, the effects of these increases on leatherback turtles are expected to be unmeasurable. As a result, the cumulative effects of 120 LNG carriers transiting the marine analysis area combined with reasonably foreseeable non-Federal projects are expected to be insignificant.

Critical Habitat

Critical habitat has been designated within 25,004 square miles along the Washington and Oregon coasts from Cape Blanco, Oregon to Cape Flattery, Washington (NMFS 2012d). NMFS (2012d) defined an area (Area 2) from Cape Blanco to Cape Flattery, including most of the Oregon coast, as a principal foraging area for leatherbacks. Critical habitat coincides with nearshore waters through which LNG carriers would transit to Coos Bay and the LNG Terminal. The single PCE for this leatherback turtle critical habitat is the occurrence of prey species, primarily jellyfish, of sufficient condition, distribution, diversity, and abundance to support individual as well as population growth, reproduction, and development (NMFS 2012d).

The proposed action could affect this PCE within critical habitat in the marine analysis area if a fuel or lubricant spill occurred from a LNG carrier. As discussed above under fuel spills, NMFS (2012d) identified LNG projects and oil spills as activities that may affect the PCE by altering prey abundance and prey contamination levels. However, with their spill prevention measures, LNG carriers are not likely to contribute oil, fuel, or lubricants to the marine analysis area to the extent that would adversely affect leatherback prey species. Fuels and lubricants are kept in relatively small quantities on ships and would not result in the types of effects associated with a spill from an oil tanker.

NMFS (2012d) identified potential effects of LNG Terminal construction and operation on the leatherback critical habitat PCE, including leaks and spills, disturbance of benthic habitat, and noise. Leaks, spills, and release of contaminants could affect water quality, but effects on the PCE are not known. However, these effects, if any, would be avoided and/or minimized as described in *Preliminary Spill Prevention, Containment, and Countermeasure Plan* (appendix F.2-Construction and appendix G.2-Operation in JCEP's Resource Report 2).

NMFS (2009d) stated that "Dredging and filling associated with construction and maintenance (to allow tanker passage) could have impacts on benthic habitat and possibly the early life stages of leatherback prey resources." However, the leatherback's prey species are open-ocean, broadcast spawners with pelagic larvae. There is no information in the literature that suggests the larvae would preferentially enter Coos Bay estuary, and if they did, there is likely nothing that would cause them to preferentially settle at the LNG Terminal. Also, Shanks et al (2010 and 2011) did not report collection of significant numbers of larval scyphozoans that would support the polypoid stage of the jellyfish commonly consumed offshore by leatherback turtles. Given the aerial extent available for larval settlement and polyp development along the Oregon and Washington coast, the loss of substrate from the dredging for the LNG Terminal footprint would have no impact on leatherback foodstocks.

For the same reason that dredging would not measurably impact the larval stages of leatherback turtle's foods, noise levels associated with construction would also not measurably impact these life stages, and would therefore have no impact on leatherback food sources.

3.4.2.4 Conservation Measures

Measures to reduce ship speeds once inside the Coos Bay navigation channel to between 4 to 6 knots and within the marine analysis area when pods or large assemblages of cetaceans are observed near an underway ship would provide some protection to leatherback turtles. However, it is highly unlikely that leatherbacks or other sea turtles would be seen from a LNG carrier. Nevertheless, the same Ship-Strike Reduction Plan, including marine mammal avoidance guidelines that was described in section 3.2.1.4 (blue whale) apply to leatherback turtles.

3.4.2.5 Determination of Effects

Species

The Project **may affect** leatherback turtles because:

- leatherback turtles may occur within the marine analysis area during operation of the proposed action;
- the proposed action would increase shipping traffic (LNG carriers) within the marine analysis area; and
- the continental U.S. Pacific Coast provides important foraging habitat for this species.

However, the Project is **not likely to adversely affect** leatherback turtles because:

- there is limited evidence that leatherback turtles have been struck by ships, and a measurable increase in collision potential as a result of the proposed action is expected to be highly unlikely;
- JCEP would provide a ship strike avoidance measures package to shippers calling on the LNG Terminal that consists of multiple measures to avoid striking marine mammals, which should also benefit sea turtles;
- LNG carriers approaching Coos Bay would be traveling slowly and escorted by tractor tugs from 5 nmi offshore to the LNG Terminal, limiting impacts to foraging leatherback turtles; and
- noise produced by LNG carriers would contribute to overall noise within the marine analysis area en route to Coos Bay and increased ship noise could affect leatherback turtle behavior. However, the noise levels of the LNG carriers would be comparable to the noise levels of existing ship traffic and would be infrequent enough so as not to cause injury or result in behavioral changes.

Critical Habitat

The Project **may affect** critical habitat for the leatherback turtle because:

- the marine analysis area that would be transited by LNG carriers includes coastal marine waters between Coos Bay, Oregon and Cape Flattery, Washington, that are designated critical habitat; and

However, the Project is **not likely to adversely affect** critical habitat for the leatherback turtle because:

- disturbance of benthic habitats within Coos Bay due to dredging would be of sufficiently short duration and small scale relative to the area available for settlement of larvae of the scyphozoan prey species within Area 2 that effects on PCE 1 would be unmeasurable and would therefore be are insignificant.

3.4.3 Olive Ridley Turtle

3.4.3.1 Species Account and Critical Habitat

Status

Olive ridley turtles were listed as threatened, except for the breeding colony populations on the Pacific coast of Mexico, which were listed as endangered, under the ESA on July 28, 1978 (FWS 1978).

Threats

Direct threats to the species include the harvesting of sea turtles and their eggs and incidental capture in fishing gear (NMFS 2017f). Olive ridley turtle eggs were collected at first by indigenous people and then for economic gain to sell in markets once the eggs were found to have commercial value (NMFS and FWS 1998c). Another market was created that used olive ridley turtle leather that aided in the demise and ultimately the listing of the olive ridley turtle as threatened/endangered (NMFS and FWS 1998c).

Natural disasters, debris entanglement and ingestion, and incidental take from domestic fisheries are listed as minor threats to olive ridley turtles (NMFS and FWS 1998c). Primary threats to olive ridley turtles off the continental U.S. Pacific Coast include incidental take from commercial fishing and boat collisions usually involving smaller boats (NMFS and FWS 1998c). The more frequent occurrence of El Niño and general warming trends in the Pacific may be the reason that the zooplankton in the California Current are declining, resulting in the reduction of higher level vertebrates and other foods for the turtles to forage on (Plotkin 1995).

Species Recovery

A recovery plan was issued in 1998. The recovery goal (NMFS and FWS 1998c) is to delist the species, and the plan listed the following necessary actions:

- Minimize incidental mortalities of turtles by commercial fishing operations;
- Support the efforts of Mexico and the countries of Central America to census and protect nesting olive ridleys, their eggs, and nesting beaches; and
- Identify stock home ranges using DNA analysis.

The stepdown outline in the recovery plan included the following recommendations:

- Protect and manage turtles on nesting beaches;
- Protect and manage nesting habitat;
- Protect and manage olive ridley populations in the marine habitat;
- Protect and manage marine habitat, including foraging habitats;

- Develop standards for the care and maintenance of sea turtles, including diet, water quality, tank size, and treatment of injury and disease;
  - Establish a catalog of all captive sea turtles to enhance use for research and education.
  - Designate rehabilitation facilities;
  - Support existing international agreements and conventions to ensure that turtles in all life-stages are protected in foreign waters;
  - Encourage ratification of CITES for all non-member Pacific countries, compliance with CITES requirements, and removal of sea turtle trade reservations held by member nations;
  - Develop new international agreements to ensure that turtles in all life-stages are protected in foreign waters; and
- Develop or continue to support informational displays in airports that provide connecting legs for travelers to the areas, which support olive ridleys.

Life History, Habitat Requirements, and Distribution

The olive ridley is primarily a pelagic sea turtle, but does occasionally inhabit coastal areas such as bays and estuaries. Olive ridleys undertake an annual migration from open-ocean foraging grounds to coastal breeding and nesting grounds. Olive ridley turtles are well known for their arribada behavior where hundreds to tens of thousands of ridley turtles emerge synchronously from the ocean over a few days to nest in close proximity (NMFS 2017f).

Olive ridleys have been observed as far as 2,400 miles from shore. Adult turtles are small compared to other sea turtles, with an average weight of approximately 100 pounds. The olive ridley feeds on a variety of food items, including algae, lobster, crabs, tunicates, mollusks, shrimp, and fish. Females nest each year after reaching sexual maturity at about age 15. They nest one to three times per season, producing clutches of approximately 100 eggs each time. Incubation of the eggs generally takes between 50 and 60 days.

Population Status

The olive ridley is considered the most abundant sea turtle in the world, with an estimated 800,000 females nesting annually. However, there has been an estimated 50 percent reduction in population since the 1960s (Marine Turtle Specialist Group 2004 in NMFS 2017f). The eastern Pacific population that nests in El Salvador, Guatemala, Costa Rica, and Panama has declined since the 1970s. However, since Mexico banned harvest of nesting females and eggs, the nesting population at La Escobilla, Oaxaca, Mexico increased from 50,000 nests in 1988 to more than 1 million nests in 2000 (NMFS 2017f). At-sea estimates of density and abundance of olive ridley turtles were conducted along the Mexico and Central American coasts from 1992 to 2006. The yearly weighted average was 1.39 million in the eastern Pacific and consistent with increased nesting prior to 2007 (NMFS and FWS 2007b).

Critical Habitat

Critical habitat has not been designated for this species.

3.4.3.2 Environmental Baseline

Analysis Area

The analysis area applicable to olive ridley turtles is the area directly off of Coos Bay out to the continental shelf break, which is represented as a depth of 200 meters, the same marine analysis area as described above for green sea turtles and blue whales (see figure 2.1.1-2).

Species Presence

At-sea occurrences in waters under U.S. jurisdiction are limited to the West Coast of the continental United States and Hawaii, where the species is rare, but possibly increasing. This species does not nest in the United States, but during feeding migrations, olive ridley turtles nesting in the East Pacific may disperse into waters off the Pacific west coast as far north as Oregon (FWS 2013f). Olive ridleys have occasionally been killed by gill-nets and boat impacts as well as cold-stunning (or cold-stranding due to hypothermia by rapid decline of water temperatures) in Oregon and Washington (NMFS and FWS 1998c). Based on sightings off the Oregon coast, olive ridley turtles may occasionally occur in the marine analysis area.

Habitat

Little is known about the abundance and distribution of olive ridley turtles in the northeastern Pacific. Important foraging grounds have not been identified although forage areas most likely exist along the coast of Baja California and Southern California (NMFS and FWS 1998c). Less is known about the potential importance of Oregon waters and the marine analysis area to olive ridley turtles.

Critical Habitat

Critical habitat has not been designated for this species.

3.4.3.3 Effects of the Proposed Action

Direct and Indirect Effects

Direct effects of the proposed action include injury and/or mortality due to ship strikes, underwater ship noise, and potential adverse effects from fuel spills at sea. These effects are addressed below.

<u>Ship Strikes by LNG Carriers</u>

The proposed action would result in increased shipping traffic and may increase potential vessel strikes to olive ridley turtles within the marine analysis area. Boat collisions are listed as a moderate problem for olive ridley turtle recovery off the continental U.S. Pacific Coast (NMFS and FWS 1998c). Sea turtles can be injured or killed when struck by a boat, especially by an engaged propeller. Risk of collision with sea turtles increases with increased vessel speed (Hazel et al. 2007), as discussed for green sea turtles, above. However, methods for reducing boat collisions are not included in recovery objectives, and based on their warm water requirements, olive ridley sea turtles are likely only occasional, transient visitors to waters as far north as Oregon.

The proposed action is expected to increase traffic by 240 additional ship transits through the marine analysis area each year of operation (inbound and outbound transits by 120 LNG carriers). Given the low population and occurrence of the olive ridley turtles in Oregon coastal waters and current estimate of vessel traffic, the addition of 240 LNG carrier transits through the marine analysis area is not expected to result in measurable additional ship strike-related mortality or injury to olive ridley turtles. However, lack of ship-strike incidences to sea turtles in general or frequencies of collision precludes any estimate of effects to olive ridley turtles of additional vessel traffic due to LNG carriers.

Underwater Noise

As with green sea turtles, the same hearing sensitivity is assumed to be the case for olive ridley turtles, and the effects are expected to be similar. See section 3.4.1, Green Turtle, above for a full discussion of these effects. With the existing levels of background shipping noise and the expected increase in shipping traffic, effects by LNG carrier related noise on olive ridley turtles are possible in the marine analysis area but the noise would be commensurate with existing noise levels and would not be expected to cause injury.

Fuel Spills

Oil, fuel, or lubricant spills from an LNG carrier at sea could impact both olive ridley turtles and forage species such as benthic invertebrates and fish as described above for green turtles. However, these products are kept in relatively small quantities onboard LNG carriers. Additionally, LNG carriers carry spill kits to prevent or minimize the release of oil, fuel, and lubricants as described under blue whales in section 3.2.1.3. As a result, effects of oil, fuel, and lubricants on loggerhead turtles are expected to be insignificant and discountable.

Cumulative Effects

In addition to the fishing fleet housed in Charleston Marina, current commercial traffic into Coos Bay includes about 50 deep-draft cargo ships and 50 barges. However, even with the addition of 120 LNG carriers per year visiting the LNG Terminal, commercial ship traffic into Coos Bay would probably not reach historic levels.

Also, as discussed above for blue whales, it appears that the background rate of spills off the Oregon coast by fishing vessels, recreation vessels, and other vessel types is generally low, a frequency that would be expected to continue into the foreseeable future. With their double hulls, onboard spill kits, and spill prevention measures, LNG carriers are not likely to contribute to oil spills in the marine analysis area or waterway to the extent that may affect aquatic species.

As a result of this projected increase in vessel traffic, threats from ship strikes, underwater noise, and the effects of fuel spills are likely to increase. However, given that olive ridley turtles occur infrequently in the marine analysis area, cumulative effects are not expected even if an increasing trend in vessel traffic is observed, because any effects are expected to be unmeasurable and thus insignificant.

Critical Habitat

No critical habitat would be affected by the proposed action as none has been designated.

3.4.3.4 Conservation Measures

Measures to reduce ship speeds once inside the Coos Bay navigation channel to between 4 to 6 knots and within the marine analysis area when pods or large assemblages of cetaceans are observed near an underway ship would provide some protection to olive ridley turtles. However, it is highly unlikely that olive ridleys or other sea turtles would be seen from a LNG carrier. Nevertheless, the same Ship-Strike Reduction Plan, including marine mammal avoidance guidelines, that was described in section 3.2.1.4 (blue whale) applies to olive ridley turtles.

3.4.3.5 Determination of Effects

Species

The Project **may affect** olive ridley turtles because:

- olive ridley turtles may occur within the marine analysis area during operation of the proposed action; and
- the proposed action would increase shipping traffic (LNG carriers) within the marine analysis area.

However, the Project is **not likely to adversely affect** olive ridley turtles because:

- the increase in annual ship traffic due to the proposed action is expected to cause an immeasurable increase for potential ship strikes to olive ridley turtles;
- JCEP would provide a ship strike avoidance measures package to shippers calling on the LNG Terminal that consists of multiple measures to avoid striking marine mammals, which should also benefit sea turtles;
- LNG carriers approaching Coos Bay would be traveling slowly and escorted by tractor tugs from 5 nmi offshore to the LNG Terminal; and
- noise produced by LNG carriers would contribute to overall noise within the marine analysis area en route to Coos Bay and increased ship noise could affect olive ridley turtle behavior. However, JCEP expects the noise levels of the LNG carriers would be comparable to the noise levels of existing ship traffic and would be infrequent enough so as not to cause injury or result in behavioral changes.

Critical Habitat

No critical habitat has been designated or proposed for the olive ridley turtle.

3.4.4 Loggerhead Turtle

3.4.4.1 Species Account and Critical Habitat

Status

Loggerhead turtles were listed as threatened under the ESA in 1978 (FWS 1978). In 2011, NMFS (2011e) published a final rule in which the agencies determine loggerhead sea turtles are composed of nine DPSs distributed worldwide; four DPSs are listed as threatened and five are listed as endangered. The North Pacific Ocean DPS is listed as endangered (NMFS 2017g).

Threats

The two biggest threats to the loggerhead turtle are incidental capture in fishing gear and directed harvesting. There is no information about direct take of the loggerhead turtle, although is it assumed to be nonexistent in the continental U.S. Pacific Coast because of the species' rarity. Reasons for listing the loggerhead turtle include direct harvest in the Bahamas, Cuba, and Mexico as well as incidental capture of turtles in commercial fishing gear (NMFS 2017g).

The primary threats to loggerhead turtles on the continental U.S. Pacific Coast include natural disasters and incidental take from commercial fishing operations (NMFS and FWS 1998d). Minor threats to loggerhead turtles on the continental U.S. Pacific Coast include natural disasters, environmental contaminants, debris entanglement and ingestion, and power plant entrapment (NMFS and FWS 1998d). Threats with an unknown degree of significance on the continental U.S. Pacific Coast include predation, boat collision, and oil exploration and development (NMFS and FWS 1998d). Dredging is listed as another important potential threat to loggerhead turtles, as they spend much of their time in continental shelf waters closer to shoreline looking for food (Plotkin 1995).

Species Recovery

A recovery plan was issued on May 22, 1998 (NMFS and FWS 1998d). The recovery goal is to delist the species, and the plan listed the following necessary actions:

- Reduce incidental capture of loggerheads by coastal and high seas commercial fishing operations;
- Establish bilateral agreements with Japan and Mexico to support their efforts to census and monitor loggerhead populations and to minimize impacts of coastal development and fisheries on loggerhead stocks;
- Identify stock home ranges using DNA analysis;
- Determine population size and status (in U.S. jurisdiction) through regular aerial or on-water surveys; and
- Identify and protect primary foraging areas for the species.

The stepdown outline in the recovery plan included the following recommendations:

- Protect and manage turtles on nesting beaches;
- Protect and manage nesting habitat;
- Protect and manage loggerhead populations in the marine habitat;
- Protect and manage marine habitat, including foraging habitats;
- Develop standards for the care and maintenance of sea turtles, including diet, water quality, tank size, and treatment of injury and disease;
- Establish a catalog of all captive sea turtles to enhance use for research and education;
- Designate rehabilitation facilities;
- Support existing international agreements and conventions to ensure that turtles in all life-stages are protected in foreign waters;
- Encourage ratification of CITES for all non-member Pacific countries, compliance with CITES requirements, and removal of sea turtle trade reservations held by member nations;

- Develop new international agreements to ensure that turtles in all life-stages are protected in foreign waters; and
- Develop or continue to support informational displays in airports and other ports of call that provide connecting legs for travelers to the area.

Life History, Habitat Requirements, and Distribution

Loggerhead turtles occur throughout temperate and tropical regions of the Atlantic, Pacific, and Indian Oceans. They are the most abundant sea turtle found in U.S. coastal waters, although they are much more prevalent on the Atlantic than Pacific Coasts, with major nesting areas being present in Florida. In the North Pacific, loggerhead nesting has only been documented in Japan but may also occur on beaches of the South China Sea (NMFS 2011e). Turtles hatching on Japanese beaches enter the Kuroshio and North Pacific Currents and develop during migration; some reach the eastern Pacific and Baja California. Foraging areas have been documented off the coast of Baja California, Mexico (NMFS 2011e). Adult loggerheads typically prey on benthic invertebrates in hard bottom habitats, although fish and plants are occasionally taken (NMFS and FWS 1998d). Evidence indicates that loggerhead turtles hatching in Japan remain in the North Pacific Basin for their entire life cycle, never crossing the equator into the South Pacific Basin (NMFS 2011e).

Loggerheads reach sexual maturity at around 35 years of age. In the southeastern United States, mating occurs in late March to early June and females lay eggs between late April and early September. Females generally lay three to five nests per season. The eggs incubate approximately 2 months before hatching between late June and mid-November. Hatchlings move from their nest to the surf, swim and are swept through the surf zone, and continue swimming away from land for about one to several days. Post-hatchlings within this habitat are float-and-wait foragers feeding on a wide variety of floating food items. From these relatively nearshore habitats, juvenile turtles are swept into the open ocean by currents. Between the ages of 7 and 12 years, oceanic juveniles migrate to nearshore coastal areas where they remain until reaching adulthood.

Population Status

In the United States, loggerhead turtles lay an estimated 68,000 to 90,000 eggs per year on the east and Gulf coasts. There is no known nesting of loggerhead turtles on the U.S. Pacific Coast. Occasional cold-strandings occur in Washington and Oregon and incidental take by fisheries probably occurs (NMFS and FWS 1998d). In the eastern Pacific, loggerheads have been reported as far north as Alaska. In the U.S., occasional sightings are reported from the coasts of Washington and Oregon, but most records are of juveniles off the coast of California. The west coast of Mexico, including the Baja Peninsula, provides critically important developmental habitats for juvenile loggerheads. Records of females in the North Pacific Oceans DPS nesting on Japanese beaches indicate numbers increased from the late 1990s through 2005 but declined in 2006 and 2007 (Conant et al. 2009).

Critical Habitat

Critical habitat has not been designated for this species.

3.4.4.2 Environmental Baseline

Analysis Area

The analysis area applicable to loggerhead turtles is the area directly off Coos Bay out to the continental shelf break, which is represented as a depth of 200 meters, the same marine analysis area as described above for green turtles and blue whales (see figure 2.1.1-2).

Species Presence

Loggerhead turtles are rarely sighted along the Pacific Coast near the Project area. Individuals found in western US Pacific Coast waters likely originate on Japanese nesting grounds (NMFS and FWS 1998d). In the United States, occasional sightings are reported from the coasts of Washington and Oregon, but most records are of juveniles off the coast of California. The most recent record of a loggerhead in Oregon waters was on February 13, 2017 of a nearly comatose individual that died shortly after being rescued by the Oregon Coast Aquarium (KCBY 2017). Therefore, based on sightings and documented strandings, loggerhead turtles are likely infrequent visitors to the marine analysis area. The California/Oregon (CA/OR) drift gillnet fishery (for swordfish and thresher shark) was observed to incidentally capture 17 loggerheads (12 released alive, one injured, and four killed) from 1990 to 2000. Based on a worst-case scenario, NMFS estimated that a maximum of 33 loggerheads in a given year are possibly incidentally taken by the CA/OR drift gillnet fleet (Conant et al. 2009).

Habitat

The fact that juveniles are captured incidentally in longlines and driftnets in the pelagic Pacific indicates that the species' range includes coastal and pelagic waters (NMFS and FWS 1998d). The potential importance of Oregon waters and the marine analysis area to loggerhead turtles is unknown. Loggerheads are likely to move into the U.S. Pacific coast from Baja California as they follow preferred prey species, the pelagic red crab (Conant et al. 2009).

Critical Habitat

Critical habitat has not been established for this species.

3.4.4.3 Effects of the Proposed Action

Direct and Indirect Effects

Direct effects of the proposed action include injury and/or mortality due to ship strikes, underwater ship noise, and potential adverse effects from fuel spills. Dredging for the Navigation Reliability Improvements, LNG slip and access channel could also affect loggerhead turtles if they are present in Coos Bay. These effects are addressed below.

<u>Ship Strikes by LNG Carriers</u>

The proposed action would result in increased shipping traffic and may increase potential vessel strikes to loggerhead sea turtles within the analysis area. However, the largest threat to loggerhead turtles outside of their nesting grounds is entanglement in gill-nets and other incidental take. Boat collisions are listed as a threat with unknown significance to the recovery of loggerhead populations (NMFS and FWS 1998d). However, risk of collision with sea turtles increases within increased vessel speed (Hazel et al. 2007), as discussed for green sea turtles, above.

The proposed action is expected to increase traffic by 240 additional ship transits through the marine analysis area each year of operation (inbound and outbound transits by 120 LNG carriers). Given the low population and occurrence of the loggerhead turtles in Oregon coastal waters and current estimate of vessel traffic, the addition of 240 LNG carrier transits through the marine analysis area is not expected to result in measurable additional ship strike-related mortality or injury to loggerhead turtles. However, lack of ship-strike incidences to sea turtles in general or frequencies of collision precludes any estimate of effects to loggerhead turtles of additional vessel traffic due to LNG carriers.

Underwater Noise

Loggerhead sea turtles can detect sound and their hearing is most sensitive to lower frequencies below 1000 Hz (Bartol et al. 1999; Martin et al. 2012), within the same range of low frequencies generated by ships and sounds generated by large baleen whales (Würsig and Richardson 2009). Effects of underwater noise to loggerhead sea turtles are expected to be similar to those described above under the green turtle (section 3.4.1). With the existing levels of background shipping noise, effects by project LNG tanker-related noise on loggerhead sea turtles are possible in the marine analysis area but the noise would be commensurate with existing noise levels and would not be expected to cause injury.

Fuel Spills

Environmental contaminants are listed as a minor threats to loggerhead turtles on the continental U.S. Pacific Coast (NMFS and FWS 1998d). Oil, fuel, or lubricant spills from an LNG carrier at sea could impact both loggerhead turtles and forage species such as benthic invertebrates and fish as described above for green turtles. However, these products are kept in relatively small quantities onboard LNG carriers. Additionally, LNG carriers carry spill kits to prevent or minimize the release of oil, fuel, and lubricants as described under blue whales in section 3.2.1.3. As a result, effects of oil, fuel, and lubricants on loggerhead turtles are expected to be insignificant and discountable.

Dredging

Dredging is listed as an important potential threat to loggerhead turtles, as they spend much of their time in continental shelf waters closer to shoreline looking for food (Plotkin 1995) and adult loggerheads typically prey on benthic invertebrates (NMFS and FWS 1998d). However, because loggerhead turtles are not likely to occur either offshore or within Coos Bay, there is essentially no potential that dredging activity would affect loggerhead individuals or have an effect on the population of loggerheads.

Cumulative Effects

In addition to the fishing fleet housed in Charleston Marina, current commercial traffic into Coos Bay includes about 50 deep-draft cargo ships and 50 barges. While this may remain constant for the near term, in the future non-fishing commercial traffic into Coos Bay may increase if the Port is able to make its planned improvements to attract new customers. However, even with the addition of 120 LNG carriers per year visiting the LNG Terminal, commercial ship traffic into Coos Bay would probably not reach historic levels.

As a result of this projected increase in vessel traffic, , threats from ship strikes, underwater noise, and the effects of fuel spills are likely to increase. However, as loggerhead turtles are likely infrequent, transient visitors to the analysis area and the Oregon coast, cumulative effects from 120 LNG carriers transiting the analysis area combined with reasonably foreseeable non-federal projects are expected to be insignificant and discountable.

Critical Habitat

No critical habitat would be affected by the proposed action; none has been designated.

3.4.4.4 Conservation Measures

Measures to reduce ship speeds once inside the Coos Bay navigation channel to between 4 to 6 knots and within the marine analysis area when pods or large assemblages of cetaceans are observed near an underway ship would provide some protection to loggerhead turtles. However, it is highly unlikely that loggerheads or other sea turtles would be seen from a LNG carrier. Nevertheless, the same Ship-Strike Reduction Plan, including marine mammal avoidance guidelines, that was described in section 3.2.1.4 (blue whale) apply to loggerhead turtles.

3.4.4.5 Determination of Effects

Species

The Project **may affect** loggerhead turtles because:

- loggerhead turtles may occur within the analysis area during operation of the proposed action; and
- the proposed action would increase shipping traffic (LNG carriers) within the analysis area.

However, the Project is **not likely to adversely affect** loggerhead turtles because:

- whether or not loggerhead turtles have been struck by ships is unknown but is expected to be highly unlikely;
- the increase in annual ship traffic due to the proposed action is expected to cause an immeasurable increase for potential ship strikes to loggerhead turtles;
- JCEP would provide a ship strike avoidance measures package to shippers calling on the LNG Terminal that consists of multiple measures to avoid striking marine mammals, which should also benefit sea turtles;
- LNG carriers approaching Coos Bay would be traveling slowly and escorted by tractor tugs from 5 nmi offshore to the LNG Terminal; and
- noise produced by LNG carriers would contribute to overall noise within the analysis area en route to Coos Bay and increased ship noise could affect loggerhead turtle behavior. However, the noise levels of the LNG carriers would be comparable to the noise levels of existing ship traffic and would be infrequent enough so as not to cause injury or result in behavioral changes.

Critical Habitat

No critical habitat has been designated or proposed for the loggerhead turtle.

3.4.5 Oregon Spotted Frog

3.4.5.1 Species Account and Critical Habitat

Status

The Oregon spotted frog was listed as threatened under the ESA in August 2014 (FWS 2014e). The species had been proposed for listing in August 2013 (FWS 2013h), and petitioned for listing in May 2004 with a positive (warranted but precluded) 90-day finding issued in 2005, and had been a candidate species since then with Listing Priority of 2 (imminent with high magnitude of threat, see FWS 2011e).

Threats

Oregon spotted frogs may be extirpated from as much as 90 percent of their historically documented range including all historical locations in California (FWS 2014e). Thirty to 85 percent of the species' wetland habitats have been lost across its range. Sources of loss include draining wetlands, water diversions, conversion of wetlands to agriculture and livestock grazing, developments adjacent to occupied habitats that alter seasonal hydrology (through creation of impervious surfaces), and occurrence of droughts which have become more frequent in parts of the species' range. Also, riverine functions that promote early successional wetland habitats have been altered including connectivity with floodplains. Beaver activities had contributed to historical mosaic of aquatic habitats and fires burning in summer influenced shallow water breeding habitats the following spring (FWS 2013h).

Introductions of exotic species, including reed canarygrass that degrades native wetland vegetation, and nonnative predators including bullfrogs and warm water fish species have been and continue to threaten the species. Chytrid fungus infections have been documented in Oregon spotted frog populations in all of the sites sampled, including five sites located in the Klamath Basin (Pearl et al. 2009). Declines in various amphibian populations have been associated with fungal infections and may have contributed to the demise of Oregon spotted frog populations although some populations appear to be resistant (Padgett-Flohr and Hayes 2011). There may be additional pathogens that affect Oregon spotted frogs (FWS 2013h).

Species Recovery

The species has been listed as threatened; however, no recovery plan has been published. A Conservation Agreement to conserve Oregon spotted frogs in the Klamath Basin has been developed by the FWS, Forest Service, and BLM (FWS et al. 2010) with the objectives to:

> "1) manage occupied habitat in a manner that sustains and/or restores its ability to support Oregon spotted frog populations; 2) stabilize or increase populations within the Klamath Basin; 3) reduce threats; and 4) increase distribution among available suitable habitats by restoring or creating habitat."

Implementing the conservation agreement has focused on a bullfrog eradication program on Crane Creek since bullfrogs appeared in 2010, and controlling and reducing bullfrogs and analyzing the gut contents of bullfrogs at all life stages on BLM lands at Wood River. While the number of bullfrogs removed and seen at that site has decreased, bullfrog removal has also focused on areas outside the Oregon spotted frog site that are considered to be the strongest source areas for movement into the Oregon spotted frog site (FWS 2013h). Despite these efforts, bullfrogs continue to persist in these Oregon spotted frog habitats in the Klamath Basin (FWS 2013h).

Life History, Habitat Requirements, and Distribution

The current range of Oregon spotted frogs extends from the Fraser River subbasin in southern British Columbia (Haycock 2000) and adjacent areas in Whatcom County, Washington, south through the Puget Trough lowlands, through the Willamette Valley, to southeast Oregon including Jackson and Klamath counties, and adjacent areas in the Pit River subbasin of northern California (FWS 2011e).

Spotted frogs inhabit perennial water bodies such as springs, ponds, lakes or slow moving streams and are usually associated with nonwoody, herbaceous wetland vegetation communities composed of sedges, rushes and grasses (Leonard et al. 1993). Several aspects of the Oregon spotted frog's life history have been proposed as contributing to the species' vulnerability to habitat alterations (FWS 2011e): 1) communal egg laying at sites used year after year restricts the number of reproductive sites; 2) the species' warm water requirement results in habitat overlap with introduced warm water fish; 3) the active season warm water requirement may limit suitable habitat in the cool climates of the Pacific Northwest; 4) the species may be vulnerable to the potential loss or alteration of springs used for overwintering; and 5) changes that increase deep, permanent water components are likely to favor establishment of non-native bullfrogs and fish, both of which may be detrimental to Oregon spotted frogs.

In lower elevations of Washington and Oregon, breeding occurs during February and March; at higher elevations breeding occurs in late May or early June (Leonard et al. 1993). Oregon spotted frogs typically oviposit communally; males may gather in large groups at a location and females lay eggs adjacent to or attached to other egg masses which are only partially submerged. These aggregations can contain eggs from 100 or more females in larger populations (FWS 2011e). Spotted frogs use traditional oviposition sites, year after year. Such sites may have limited availability because of unique characteristics and adults may have limited flexibility to switch sites if they become unsuitable. That possibility makes the Oregon spotted frog particularly vulnerable to habitat changes at oviposition sites (FWS 2011e).

Population Status

Population estimates in most subbasins inhabited by Oregon spotted frogs are insufficient to derive any trends (FWS 2013h). The best available information indicates declining populations in the lower Fraser River in British Columbia and Middle Klickitat subbasin in Washington, but an undetermined trend in Oregon (FWS 2013h).

In 2012, there were an estimated 7,368 breeding adults at five extant population sites in Washington and 12,847 breeding adult Oregon spotted frogs at 8 extant population sites in Oregon (FWS 2014e). In Oregon the species’ extant distribution includes 22 sites in the Central Oregon Cascades (with the largest population of 500 to 2,500 breeding females at two sites) and nine sites in the Klamath Basin (FWS 2011e). In 2005, personnel with the Forest Service surveyed 28 different sites in Lake, Klamath, and Jackson counties but no new Oregon spotted frogs were found. Data from the Klamath Basin suggests that one population has declined since 2000, two populations appear stable, and five sites do not have enough data to determine trend, including the Buck Lake site. However, FWS (2014e) note that surveys conducted at Buck Lake suggest a population decline and have documented most recently small numbers of egg masses

(38 masses in 2010), or the equivalent of 76 breeding individuals (male and female) (cited in FWS 2014e). The minimum population estimate for this Klamath sub-basin was estimated to be 112 breeding individuals in 2014 suggesting drastic population declines since 1998 (FWS 2014e). The Buck Lake site is isolated from all other Oregon spotted frog populations with little or no chance for genetic interchange or re-colonization; there is no hydrologic connectivity to other occupied habitats in the Klamath Basin (FWS 2011e).

Critical Habitat

Critical habitat for the Oregon spotted frog was finalized in May 2016 (FWS 2016c). In June 2014, FWS proposed to expand four of the proposed critical habitat units based on new information, including occupancy of those areas by Oregon spotted frogs (FWS 2014e). The expanded critical habitat units are included in the final rule. The units include critical habitat in Washington (Units 1 through 6) and in Oregon (Units 7 through 14). The Buck Lake site is within designated critical habitat Unit 14: Upper Klamath, Oregon. The Upper Klamath Unit 14 consists of 262 acres of lakes and creeks in Klamath and Jackson Counties, Oregon. In Klamath County, Oregon, Buck Lake critical habitat includes seasonally wetted areas adjacent to the western edge of Buck Lake encompassing Spencer Creek downstream due west of Forest Service Road 46, three unnamed springs, and Tunnel Creek (FWS 2016c), shown in figure 3.4.5-1.

FWS (2016c) determined that the PCEs specific to the Oregon spotted frog are:

1. PCE-1 (applicable to the following seasonal life stage periods – Nonbreeding (N), Breeding (B), Rearing (R), and Overwintering Habitat (O)) is ephemeral or permanent bodies of freshwater, including, but not limited to natural or manmade ponds, springs, lakes, slow-moving streams, or pools or oxbows within or adjacent to streams, canals, and ditches, that have one or more of the following characteristics:
    - Inundated for a minimum of 4 months per year (B, R) (timing varies by elevation but may begin as early as February and last as long as September);
    - Inundated from October through March (O);
    - If ephemeral, areas are hydrologically connected by surface water flow to a permanent water body (e.g., pools, springs, ponds, lakes, streams, canals, or ditches) (B, R);
    - Shallow water areas (less than or equal to 30 centimeters (cm) (12 inches), or water of this depth over vegetation in deeper water (B, R);
    - Total surface area with less than 50 percent vegetative cover (N);
    - Gradual topographic gradient (less than 3 percent slope) from shallow water toward deeper, permanent water (B, R);
    - Herbaceous wetland vegetation (i.e., emergent, submergent, and floating leaved aquatic plants), or vegetation that can structurally mimic emergent wetland vegetation through manipulation (B, R);
    - Shallow water areas with high solar exposure or low (short) canopy cover (B, R);
    - An absence or low density of nonnative predators (B, R, N).
2. PCE 2 is aquatic movement corridors. Ephemeral or permanent bodies of fresh water that have one or more of the following characteristics:
    - Less than or equal to 5 kilometers (3.1 miles) linear distance from breeding areas;

- Impediment free (including, but not limited to, hard barriers such as dams, biological barriers such as abundant predators, or lack of refugia from predators).

3. PCE 3 is refugia habitat. Nonbreeding, breeding, rearing, or overwintering habitat or aquatic movement corridors with habitat characteristics (e.g., dense vegetation and/or an abundance of woody debris) that provide refugia from predators (e.g., nonnative fish or bullfrogs).

3.4.5.2 Environmental Baseline

Analysis Area

The analysis area for Oregon spotted frogs includes two components 1) Spencer Creek from the point where it is proposed to be crossed by the Pipeline, downstream to the maximum extent of Pipeline project effects (1,450 feet) and 2) the riparian zone associated with Spencer Creek.

Similar to listed fish species, the first component of the analysis area for Oregon spotted frogs is the Spencer Creek riverine analysis area associated with Spencer Creek and Buck Lake. This component of the analysis area includes the water column and substrate of Spencer Creek to the extent downstream of the proposed crossing where water quality could be adversely affected by turbidity generated during construction, and from sediment generated by runoff from the construction right-of-way. The associated riparian zone of Spencer Creek is included in the analysis area over the short-term during construction, and in the long-term by operation.

Construction across Spencer Creek is expected to mobilize silt, assumed to be the predominant substrate particle at the crossing location. As discussed below in the description of potential effects, the downstream distance that silt particles would be expected to settle out of the water column during construction using the proposed dam-and-pump crossing method, is estimated to be 1,450 feet (based on assumptions and estimation procedures below). Consequently, the Spencer Creek riverine analysis area would extend 1,450 feet downstream from the point of construction.

Species Presence

As of 2016, Oregon spotted frogs continued to inhabit Buck Lake. Oregon spotted frogs were first documented in 1994 at Buck Lake in the Winema National Forest and adjacent private lands in a canal on the northwestern edge of Buck Lake and on BLM lands within Tunnel Creek (Forest Service and BLM 1995), inhabiting the channelized portion of the perennial stream that enters the Buck Lake basin from the southwest. Forest Service and BLM (1995) indicated that these were the only sites in the Spencer Creek watershed likely to be inhabited by Oregon spotted frogs. However, FWS (2016c) indicated that Spencer Creek from Buck Lake downstream approximately 1.6 miles to the intersection of FS Road 46 and Clover Creek Road is also occupied by the Oregon spotted frog (FWS 2016c), including 15 acres of BLM and NFS lands and 2 acres of private land. At its closest location to the Project, this occupied habitat is 280 feet from the right-of-way, although Clover Creek Road separates the right-of-way from Spencer Creek (figure 3.4.5-1).

Pacific Connector Gas Pipeline, LP

Figure 3.4.5-1
Critical Habitat for
Oregon Spotted Frog at Buck Lake

Klamath County Oregon

A mark-recapture study to assess the Oregon spotted frog population in Buck Lake was conducted between 1995 and 1997 by Marc Hayes. The study results provided a population estimate of about 519 adults (with a range of 0 to 1,499, derived from 95 percent confidence intervals; Lerum (2012). Demographic information from this study showed limited evidence of recruitment likely attributable to the presence of resident brook trout (FWS 2011e). Observations of adult Oregon spotted frogs made between 1994 and 2001 ranged from 25 to 176, no adult frogs were observed in 2005 or 2009 (FWS 2011e; see figure 3.4.5-2). Since Hayes' study, various Forest Service, BLM, FWS, and USGS personnel have sporadically resurveyed this population documenting continued presence through 2011 (Lerum 2012). Since 2006, egg mass surveys have been conducted in addition to searches for adult frogs. Results are included in figure 3.4.5-2 and range from 6 egg masses in 2011 to 38 egg masses counted in 2010. However, the locations and search efforts varied from year to year, making inferences about trends based on egg masses counted inappropriate (Lerum 2012).

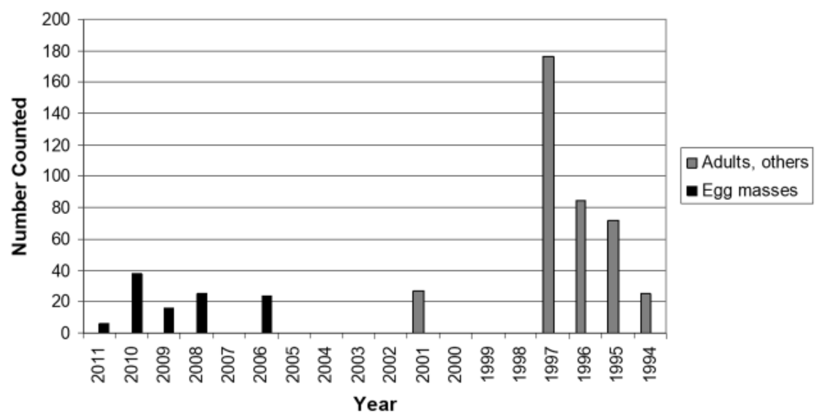

Figure 3.4.5-2 Observations of Oregon Spotted Frog Adults (Including Juveniles and Metamorphs) and Egg Masses at Buck Lake (Sources: FWS 2011e; Lerum 2012)

Oregon spotted frogs at Buck Lake have been consistently monitored from 2012 to 2016, along with other populations in the Oregon Cascades (Adams et al. 2017). Observations of frogs at two sites in Buck Lake and one in Tunnel Creek (both in critical habitat Unit 14) indicate some variability in counts for each of several life stages but adults and larva or juveniles were found each year. Numbers of adults were highest in 2016 (table 3.4.5-1.

Habitat

Historically, Buck Lake was likely a large, shallow marsh fed by springs and streams. Two perennial streams, Spencer Creek and Tunnel Creek, flow into Buck Lake but the basin is currently a meadow with drainage ditches, and at least two impounded areas fed by springs (Lerum 2012). ORBIC (2017c) has mapped Oregon spotted frog habitat at Buck Lake to include Spencer Creek from its inflow at the lake to approximately 6,100 feet upstream to where Spencer Creek passes through a culvert beneath Clover Creek Road. That segment of Spencer Creek is almost equally subdivided into Buck Marsh, closest to the highway, and Buck Meadow, closest to Buck Lake (Lerum 2012). Spencer Creek flows through Buck Marsh and Buck Meadow on Forest Service lands. Buck Marsh is fed by several springs with evidence of beaver activity and Buck Meadow is a pasture that often floods in the spring but does not stay flooded long enough to provide Oregon spotted frog breeding habitat. Further, soils in Buck Marsh are dense, possibly compacted by past heavy livestock use, and provide little water infiltration. Riparian vegetation is sparse, and is unlikely to support beaver occupancy that could help to create suitable habitat (Lerum 2012). Neither Buck Marsh nor Buck Meadow currently provide habitat for Oregon spotted frogs (Lerum 2012).

Some winters Spencer Creek freezes and flows cease. It is unknown if the site could provide overwintering habitat. It is not known exactly where Oregon spotted frogs in the Buck Lake complex overwinter. Underwater video cameras installed in 2010 and 2011 did not detect Oregon spotted frogs at suspected overwintering sites until March when frogs began to move to breeding sites (Lerum 2012).

Lerum (2012) reported on a Level II stream survey of Spencer Creek flowing through Buck Marsh and Buck Meadow conducted by the Forest Service on June 28, 2010 (Forest Service 2011 cited in Lerum 2012). Spencer Creek characteristics in this area (Reach 5) were summarized as: "a Rosgen E6 stream channel type due to its gradient and silt dominated substrate. A large portion (3500') of reach 5 was determined to be a marsh. The average wetted width (Rosgen E channel only) is 6.4 feet. The reach averages 19 pools per mile with residual pool depth of 1.2 feet. Stream banks are 98 percent stable and 2 percent unstable with sections of unstable bank along both sides of the stream. The reach had six pieces of LWD per mile (zero large/medium and six small pieces per size class). The stream side vegetation was dominated by grass forbs with an overstory of grass forbs. There are some isolated pockets of lodgepole pine. The stream runs through a very large valley dominated by marshland. A channel begins to take shape at the end of the valley up to the road crossing. There are active beaver dams in the marsh. Unidentified fish were observed throughout the reach." Typical Rosgen E6 channels (Wildland Hydrology 1994):

- are slightly entrenched (entrenchment ratio >2.2);
- have very low width to depth ratios (ratio <12);
- have high sinuosity (>1.5);
- have water surface slope gradients <2 percent; and
- channel substrate particles are predominantly silt and clay.

In 2002, lower Spencer Creek was listed by the Oregon Department of Environmental Quality (303(d) List, ODEQ 2002) as impaired due to sediment based on the formation of appreciable bottom or sludge deposits. However, there are no estimates of ambient turbidity in Spencer Creek (Forest Service and BLM 1995) although intense cattle grazing around Buck Lake has contributed to elevated sediment in the creek, probably downstream from Buck Lake. Within the watershed, the principal causes of stream sedimentation are bank erosion and delivery of sediment from roads and stream crossings (BLM 2008).

There are no long-term discharge data for Spencer Creek. Flows were measured downstream from Buck Lake from 1992 to 1998 during which annual peak flows were from 150 to 200 cubic feet per second (cfs) and summer base flows were 20 cfs, with a minimum of 5 cfs following a dry winter (BLM 2008). Peak flows in the middle portion of the Spencer Creek watershed were caused by snowmelt and rain-on-snow events.

Critical Habitat

Proposed critical habitat Unit 14 includes seasonally wetted areas adjacent to the western edge of Buck Lake encompassing Spencer Creek, three unnamed springs, and Tunnel Creek, as well as Spencer Creek downstream of Buck Lake as shown in figure 3.4.5-1. Buck Marsh and Buck Meadow are not included in the proposed critical habitat. The proposed critical habitat is approximately 6,400 feet downstream from where the Pipeline would cross Spencer Creek. The proposed critical habitat downstream of Buck Lake is approximately 280 feet overland from the right-of-way at its closest location to the Project, although Clover Creek Road separates the right-of-way from Spencer Creek at this location and there is no hydrologic connection.

There are approximately 203 acres within proposed Unit 14 at Buck Lake: approximately 53 acres are federally managed BLM and Winema National Forest land, and approximately 149 acres are privately owned (FWS 2014e). Another area, Keene Creek in Jackson County, is also included in Unit 14 but is approximately 14.5 miles from the proposed critical habitat at Buck Lake. According to FWS (2013i, page 53551), "all of the essential physical or biological features are found within the unit, but are impacted by woody vegetation succession, nonnative predators, lack of beaver, and hydrological changes. The essential features within this unit may require special management considerations or protection to ensure maintenance or improvement of the existing nonbreeding, breeding, rearing, and overwintering habitat; aquatic movement corridors, or refugia habitat, and to address any changes that could affect these features."

3.4.5.3 Effects of the Proposed Action

Direct and Indirect Effects

Construction of the Pipeline could directly and/or indirectly affect Oregon spotted frog through one or more of the following pathways:

- interference with key life history functions;
- acoustic shock from blasting pipe trench through bedrock streambeds or use of a track hoe or impact hammer if frogs are proximate to the construction site;
- turbidity generated during construction across waterbodies;
- introduction and/or re-distribution of nonnative aquatic species and pathogens;
- accidental release of fuels and entry of other petroleum products into surface waters; or
- application of herbicides to control noxious weeds near waterbodies.

Timing

State guidelines (ODFW 2008) would allow instream construction across Spencer Creek (a tributary to the Klamath River below Keno) and tributaries to Spencer Creek from July 1 through September 30. Construction during that period would avoid any downstream effects to egg masses or spotted frogs during metamorphosis in Buck Lake. Hydrostatic discharge is projected to occur in the late summer to early fall immediately following construction.

Acoustic Shock

The base material where the Pipeline is proposed to cross Spencer Creek is described as igneous rock and locally tuffaceous rock with local valley fill. There is a high potential that blasting would be needed to construct the trench across Spencer Creek if volcanic rocks cannot be excavated to the appropriate depth (GeoEngineers 2013a). Effects of underwater blasting on frogs is generally unknown although effects on frogs' lungs are expected to be similar to effects on fish with swim bladders, and would cause mortality (Keevin and Hempen 1997). Effects of underwater blasts on coho salmon are discussed below in section 3.5.3.3. The analysis in that section identified straight line distances through rock and other materials for a single shot explosive charge, of given weight, to dissipate to an overpressure standard of 2.7 pounds per square inch (psi), the threshold for non-lethal pressure for anadromous fish, and assumed to be applicable to frogs. PCGP may opt to blast across stream locations where consolidated rock makes traditional trenching methods unfeasible.

Typical trench blasting scenarios use multiple 1- to 2-pound charges separated by an 8-millisecond delay to excavate the trench. With use of 1- to 2-pound charges in rock, the set back distance (at which 2.7 psi would occur) from the blast trench to the aquatic habitat is between 34 and 49 feet (see Table 3, in ADFG 1991). Blasting would be conducted within dry streambanks isolated from the water column, most likely using dam-and-pump construction to bypass water around the dry workspace. Since no Oregon spotted frogs are expected in the vicinity of the Spencer Creek construction right-of-way, blasting is not expected to affect this species.

Suspended Sediment

Suspended sediments (turbidity) directly affect survival and growth of salmonids and other fish species, interferes with gill function, and adversely affects substrate for fish egg development (reviewed and compiled by Newcombe and Jensen 1996 and Bash et al. 2001). Effects of turbidity on frogs have not been extensively reported. Densities of three amphibian species were significantly lower in streams impacted by sediment due to road construction than in non-impacted streams (Welsh and Ollivier 1998) and relative abundances in larvae of two frog species were less in wetlands impacted by turbidity caused by livestock than non-impacted wetlands (Schmutzer et al. 2008). As summarized by Henley et al. (2000), sedimentation can reduce food availability, water and environmental quality, and habitats used by aquatic organisms resulting in decreased plant, zooplankton, and insect abundance and biomass that would affect aquatic food chains and consequently would affect frogs during different life stages.

Although background levels of suspended sediment in Spencer Creek are unknown (Forest Service and BLM 1995), construction of the Pipeline would probably mobilize particles into the water column, primarily silt which is the predominant substrate material in Spencer Creek (see above and Lerum 2012). The distance downstream that silt particles would be transported can be estimated with the following equation:

$$L = (D\ V_A) / V_S$$

where L is the transported distance downstream (in feet); D is the average depth of stream flow (in feet), V_S is the particle size-specific settling velocity (in inches or feet per second), and V_A is the average streamflow velocity (in feet per second). The settling velocity (V_S) for medium silt is 0.009 inch per second or 0.00075 feet per second (see the Wentworth Grain Size Chart, USGS 2003). The average depth of streamflow within Spencer Creek at the time of construction is unknown but, using the average wetted width of 6.4 feet (see above and Lerum 2012) and a low width to depth ratio of 10 (for Rosgen E6 channels the width to depth ratios are <12), the average depth is estimated to be 0.64 feet (8 inches).

Assuming a rectangular channel cross section, the cross-sectional area is A = 4.1 square feet (ft^2). The estimated cross-sectional area (A) can be used in Manning's Formula (Limerinos 1970; Arcement and Schneider 1989) to estimate Q, the stream discharge rate (cfs) and ultimately to estimate V_A , the average streamflow velocity. Manning's Formula is:

$$Q = A\ (k/n)\ (R^{2/3})\ (S^{1/2})$$

with estimated A = 4.1 ft^2, R is the hydraulic radius (in feet, where R = A/P, and P is the wetted perimeter in feet), S is the slope of channel (vertical feet per horizontal feet), the constant *k* equals 1.486 if English units are used but *k* equals 1 with metric units, and n is Manning's roughness coefficient (Manning's n).

For Spencer Creek, the wetted perimeter P = (2 x 0.64 feet) + 6.4 feet = 7.68 feet so that the hydraulic radius R = 0.53 feet, the slope of channel S = 0.015 (or 1.5 percent, for Rosgen E6 channels the water surface slope gradient is <2 percent). Manning's n was estimated at n = 0.070, based on a natural stream channel with sluggish reaches, weedy, and with deep pools (Chow 1959).

With these parameters estimated, the solution for Manning's Equation is Q = 6.98 cfs. With the estimate for Q, and A = 4.1 ft^2, the estimated stream velocity is $V_A = Q / A = 1.7$ feet per second.

Solving the distance-rate-time equation (above) using the following values: D = 0.64 feet, V_S = 0.00075 feet per second, and V_A = 1.7 feet per second, the estimated distance downstream (L) that silt particles would settle out of the water column would be L = 1,453 feet from the location where the Pipeline crosses Spencer Creek. That distance would fall within Buck Marsh. Currently, there are no Oregon spotted frogs inhabiting Buck Marsh although the presence of beaver activity and spring flooding could provide suitable breeding habitat (Lerum 2012). Based on current information however, sediment mobilized during construction is not expected to reach habitats occupied by frogs in Buck Lake.

Construction of the Pipeline project is not expected to increase suspended sediment in Spencer Creek downstream of Buck Lake. Although the right-of-way occurs as close as 280 feet from Spencer Creek, the right-of-way and Spencer Creek are separated by Clover Creek Road (paved road) and are not hydrologically connected. BMPs and erosion control measures should prevent sediment from the construction right-of-way from entering Spencer Creek. PCGP indicated in their ECRP (appendix F) that they would install sediment barriers "at the base of slopes adjacent to road, wetland and waterbody crossings where sediment could flow from the construction right-of-way onto the road surface or into the wetland or waterbody" and temporary erosion control structures would be inspected by the EI at least on a daily basis in areas of active construction and equipment operation. Although a major precipitation event significant enough to wash out Project erosion control devices could cause sheet flow over Clover Creek Road to carry sediment into Spencer Creek, such an event is highly unlikely and not expected to occur.

The Pipeline route would cross two tributaries to Spencer Creek at MPs 171.57 and 173.74, approximately 740 and 5,900 feet upstream of the confluence with Spencer Creek, respectively. The stream at MP 171.57 was mapped as two feet wide fanning out into a wetland/stream complex and the stream at MP 173.74 was mapped as a four-foot-wide ephemeral snowmelt-fed stream. Both would be crossed using the dry-open cut method. They are expected to be dry at the time of construction (July 1 through September 30 per ODFW 2008), and thus are not expected to contribute sediment to Spencer Creek as a result of construction.

The proposed hydrostatic discharge site at MP 169.52 is approximately 1.6 miles from Spencer Creek. An accidental release during discharge could cause the discharge water to carry sediment downstream into Spencer Creek. However, the water would be discharged at a rate to prevent scour, erosion, and sediment migration to sensitive resources such as wetlands and waterbodies, as described in the *Hydrostatic Test Plan* (appendix U). When discharged, the test water would be released into a dewatering device such as a straw bale structure or sediment bag to minimize possible peak flow effects by dissipating the energy of the test water flow, filtering the test water to avoid sedimentation, and by allowing release of the test water as sheet flow back into the ground. Additionally, the hydrostatic test water would be discharged to a vegetated upland area (greater than 150 feet from any wetland or waterbody). Effects to Oregon spotted frogs from hydrostatic discharge are not anticipated considering these procedures and BMPs, the distance between the discharge site and occupied habitat, and the extremely low likelihood of a test water spill.

Introduction of Non-Native Species and Disease

Non-indigenous aquatic species (NAS) are aquatic species that degrade aquatic ecosystem function and benefits, in some cases completely altering aquatic systems by displacing native species, degrading water quality, altering trophic dynamics, and restricting beneficial uses (Hanson and Sytsma 2001). FWS (2013j) identified warm water non-native fish (bullhead, fathead minnows), and cold water non-native brook trout that had been introduced to Buck Lake, although bullfrogs were absent. Non-native fish may limit numbers of juvenile frogs by predating larvae and/or juveniles. Bullfrogs also may act as direct predators on larval and juvenile frogs but bullfrogs are not known to occur on federal land in the Buck Lake complex (Lerum 2012). Although unlikely, introduction of bullfrogs and/or other warm water predaceous fish species could occur through hydrostatic test water discharge.

Oregon spotted frogs in Buck Lake are infected with the fungal pathogen *Batrachochytrium dendrobatidis* (Bd), which causes chytridiomycosis (Pearl et al. 2009; FWS 2013j). However, Oregon spotted frogs experimentally infected with the chytrid pathogen were able to clear the infections with no mortality suggesting some resistance to Bd (Padgett-Flohr and Hayes 2011). The fungus may infect other nonamphibian hosts (e.g., crayfish), persisting in freshwater ecosystems that are uninhabited by frogs, but infected hosts may transmit the disease to uninfected frogs (McMahon et al. 2013)

The water mold *Saprolegnia* has been suggested as one possible cause of amphibian declines in the Pacific Northwest which destroys developing Oregon spotted frog egg masses (FWS 2013h). Water-molds of the genus *Saprolegnia* have been identified in Oregon spotted frog populations in the Klamath Basin (Lerum 2012). Mortality may be caused by parasitic infections by the trematode *Ribeiroia ondatrae* that are transmitted through aquatic snails (genus *Planorbella*), an intermediate host. The infections cause limb malformations in amphibians. Human manipulation of upland areas adjacent to amphibian breeding areas and direct manipulation of the breeding areas can affect the prevalence of *Planorbella* snails and the infection rate of *Ribeiroia ondatrae* (FWS 2013h). Increased prevalence of trematodes and risks of parasitism to frogs may occur if water runoff from areas of heavy livestock use causes eutrophication, algal blooms, and increased snail abundance in frog habitats (Johnson et al. 2007). The trematode has not been documented in the Buck Lake frog population (FWS 2013i).

The risk of introducing *Saprolegnia*, *Ribeiroia ondatrae*, and/or other pathogens into Buck Lake during construction appears to be low. Pathogens might be brought to the Spencer Creek construction site if attached to machinery or if introduced by hydrostatic water discharged at a test header. The closest hydrostatic discharge location to Spencer Creek (adjacent to MP 171.07) is 1.6 miles away at MP 169.52; at that site, 2,126,306 gallons (6.53 acre feet) of test water are proposed to be discharged on the construction right-of-way. The discharge site is 2.4 miles away with intervening higher topography relative to Buck Lake; also, the Clover Creek Road intervenes and would block any flow toward the lake. Hydrostatic discharge water is not expected to reach Spencer Creek downstream of Buck Lake as described above under Suspended Sediment.

PCGP has developed BMPs to avoid the potential spread of the aquatic invasive species and pathogens of concern (see *Hydrostatic Testing Plan*, appendix U). If determined to be feasible for hydrostatic testing requirements, all water used in hydrostatic testing would be returned to its withdrawal source location after use; however, cascading water from one test section to another to minimize water withdrawal requirements may make it impractical to release water within the same watershed where the water was withdrawn. If it is not possible to return the water to the same water basin from where it was withdrawn, various water treatment methods would be used to disinfect water that would be transferred across water basin boundaries including screening/filtering, chlorine treatment, and discharge to upland sites. After hydrostatic test water withdrawal, all equipment used in the withdrawal process would be cleaned and sanitized to prevent the potential spread of aquatic invasives and pathogens from the use of this equipment in other waterbody sources (see appendix U).

Fuel and Chemical Spills

Oregon spotted frog habitat in the Buck Lake complex could be adversely affected if petroleum products were accidentally discharged into aquatic environments. Such materials are toxic to algae, invertebrates, fish and amphibians. Of the products likely to be present during construction, data compiled from a wide range of sources indicate that diesel fuels and lubricating oils are considerably more toxic to aquatic organisms than other, more volatile products (gasoline) or heavier crude oil (Markarian et al. 1994). Lytle and Peckarsky (2001) showed that release of diesel fuel in freshwater habitats significantly reduced aquatic invertebrate densities and species richness at least 3 miles downstream from the release but invertebrate densities recovered within a year. Impacts to aquatic habitats that primarily affect aquatic substrates – hence spawning, incubating and rearing habitats – can remain for much longer periods (Markarian et al. 1994).

Construction equipment used to construct the Pipeline across waterbodies can potentially release hydraulic fluid that include a variety of compounds, most commonly being mineral oil-based, organophosphate esters, and polyalphaolefins (HHS 1997). Release from machinery can occur through faulty seals, hoses, sumps and reservoirs, or general system failure. Components of mineral oil and polyalpaolefins do appear to bioaccumulate in animals whereas larger molecular constituents in organophosphate esters can concentrate in fish, primarily partitioning in fat tissue (HHS 1997). In general, toxicity of organophosphate esters is greater than either mineral oil or polyalphaolefin-based hydraulic fluids for inhalation, oral, and dermal for humans but toxicities have not been clearly described for aquatic invertebrates, fish, or amphibians and would be dependent on specific chemical components (HHS 1997).

Inadvertent spills of fluids used during construction, such as fuels and lubricants, could contaminate wetland soils and vegetation. To minimize the potential for spills and any impacts from such spills, PCGP's Spill Prevention, Containment, and Countermeasure Plan (SPCCP; see appendix L) would be implemented. In general, hazardous materials, chemicals, fuels, lubricating oils, and concrete-coating activities would be not be stored, nor would refueling operations be conducted within 150 feet of a wetland or waterbody in accordance with the FERC's *Procedures* (see appendix C) and the SPCCP (see appendix L).

Herbicide Application

Following construction, PCGP would implement a *Noxious Weed Control Plan* in part through the application of herbicides. Herbicides have the potential to cause toxic effects to different salmonid life stages and to other aquatic species, causing direct impacts, if used improperly. When herbicides are properly used according to label restrictions and BMPs to control noxious weeds, there is little to no chance of causing injury or mortality to aquatic organisms; thus the impact would likely be avoided.

PCGP has developed an *Integrated Pest Management Plan* (IPM) in consultation with the ODA, BLM and Forest Service (see appendix N to the POD, available upon request) to address the control of noxious weeds and invasive plants across the project. The BMPs would minimize the potential spread of invasive species and minimize the potential adverse effects of control treatments.

According to the Pacific Northwest Weed Management Handbook (see Peachey et al. 2007), herbicides used in forests to control brush and weed-trees could include one of the following: 2,4-D, glyphosate, imazapyr, picloram, and triclopyr, which are applied during spring or fall dormancy although triclopyr or 2,4-D was not approved use by the Winema National Forest. Clopyralid may be used during summer to control thistles, other composites, and legumes while not damaging conifers. Only herbicides that are approved for use within treated lands (private, state, or federal) would be used. In general, most impact to waterbodies occurs from direct overspray or drift of herbicides (aerial applications) as well as leaching through soils into groundwater or as they are carried by surface/subsurface runoff (Tu et al. 2001). The ester form of herbicides is more toxic to fish and other aquatic species than salt or acid forms because esters are readily adsorbed through skin and gills. Esters are also water insoluble so that they are not diluted in waterbodies (Tu et al. 2001).

Herbicides potentially used during the project breakdown over various periods of time, marked by the average half-life (the time it takes for the herbicide concentration to decline by 50 percent due to microbial metabolism –dependent on the microbial population, environmental pH, soil moisture and temperature - mineralization, and/or photolysis:

- 2,4-D—averages 10-day half-life in soils, less than 10 days in water. Salt formulations with low toxicity are registered for use against aquatic weeds. Acute exposure of 2,4-D to leopard frog tadpoles reduces their activity and feeding but does not appear to be a particularly strong threat to larvae (Ryan et al. 2006).
- Glyphosate—ranges from several weeks to years, but averages two months. In water, glyphosate is rapidly dissipated through adsorption to suspended and bottom sediments, and has a half-life of 12 days to 10 weeks. Toxicity of glyphosate-based pesticides to amphibians varies with developmental stage because there is some evidence that some formulations may interfere with metamorphosis (Howe et al. 2004).
- Imazapyr—ranges from one to five months in soil. In aqueous solutions with photodegradation the half-life may be two days. It has low toxicity to fish and algae, and submerged vegetation is not affected. Adverse effects to terrestrial and aquatic animals appear to be unlikely (Durkin and Follansbee 2004).
- Picloram – ranges from one month to three years in soil, and two to three days in water. It is characterized as slightly to moderately toxic to aquatic species, and was shown to be slightly toxic to tadpoles (Tu et al. 2001; Johnson 1976).
- Triclopyr – averages 30 days in soils, and one to four days in water. Toxicity to aquatic organisms is variable depending on life stage, pH, available sunlight, but appears to be overall low when applied correctly (Tu et al. 2001; Antunes-Kenyon and Kennedy 2004; Durkin and Follansbee 2003).

The potential for adverse effects to Oregon spotted frogs and other aquatic species by these herbicides appear to be extremely remote, especially since application would be at least 100 feet from wetlands and waterbodies unless allowed by the land manager. PCGP would not use aerial herbicide applications and would not use herbicides for general brush/tree control within the 30-

foot maintained easement. Given low toxicities and short half-lives in soil and water, expected effects of herbicides to amphibians would be discountable and insignificant.

Where weed control is necessary along the construction right-of-way, PCGP's first priority would be to employ hand and mechanical methods (pulling, mowing, biological, disking, etc.) applicable to the species to prevent the spread of potential weed infestations, where feasible. To determine if an herbicide is to be used over other control methods, PCGP would base the decision on weed characteristics and integrated weed management principles (Forest Service 2005). If herbicides are used to control noxious weed infestations, they would be used when they are the most appropriate treatment method. Spot treatments and the use of selective herbicides would be utilized to minimize impact to native or non-target species.

PCGP would employ a state or federally-licensed herbicide applicator to ensure that the appropriate herbicides are utilized for the targeted weed species during its proper phenological period and at the specified rate. The applicator would ensure that the herbicides and any adjuvants[1] are used according to the labeling restrictions and warnings, following all applicable laws and conforming to the appropriate land managing agency decision documents. The applicator would also ensure that the herbicides that are used are registered for their intended use. Permits or approvals for the use of herbicides and adjuvants on federal lands would be obtained prior to use/treatment, as detailed in the IPM (see appendix N to the POD, available upon request).

Cumulative Effects

The majority of the Oregon spotted frog analysis area is within the Winema National Forest or on lands managed by the BLM. Actions on these federal lands would require section 7 consultation and thus are not considered here.

No specific private reasonably foreseeable actions were identified within the Spencer Creek fifth-field watershed, including the Oregon spotted frog analysis area. However, ongoing grazing and timber harvests on private lands within and around Buck Lake and Spencer Creek are likely to continue. Potential impacts of grazing at this site include both the direct impacts of grazing sedimentation and trampling, as well as the indirect effect of egg mass desiccation resulting from water management techniques that drain water early in frog breeding season to stimulate grass production (FWS 2014e). However, as construction and operation of the Project are not expected to result in increased sedimentation or trampling, or changes in hydrology, to Oregon spotted frog habitat, no cumulative effects are expected. Additionally, mitigation for construction includes riparian plantings and fencing to exclude livestock in Spencer Creek upstream of Buck Lake, which would reduce sediment within the occupied habitat downstream and could potentially encourage beaver occupancy, which would help create suitable Oregon spotted frog habitat.

Critical Habitat

A portion of proposed critical habitat Unit 14 in Spencer Creek downstream of Buck Lake is within the Oregon spotted frog analysis area. Unit 14 contains all three PCEs identified by FWS

[1] Adjuvant(s) are substances added to the pesticide formulation to enhance the toxicity of the active ingredient or to make the active ingredient easier to handle.

(2013i), including suitable ephemeral or permanent bodies of freshwater (PCE1), aquatic movement corridors (PCE2), and refugia habitat (PCE3). Construction of the Project could affect PCEs within Unit 14 by impacting site hydrology or introducing nonnative predators, although these effects are not expected as described below.

The right-of-way occurs as close as 280 feet from proposed critical habitat in Spencer Creek downstream of Buck Lake; however, the right-of-way and Spencer Creek are separated by Clover Creek Road and are not hydrologically connected. As a result, construction of the Project at this location is not expected to affect hydrology within the proposed critical habitat.

As described above, the proposed hydrostatic discharge site at MP 169.52 is 1.6 miles upstream from Spencer Creek and is about 4.7 miles from the designated critical habitat in Spencer Creek and 2.38 miles (straight-line distance) from designated critical habitat in Buck Lake. An accidental release of water during hydrostatic discharge could cause the discharge water to travel downstream into Spencer Creek, temporarily altering hydrology within the proposed critical habitat, and potentially introducing nonnative aquatic predators. However, the test water would be released into a dewatering device such as a straw bale structure or sediment bag which would allow the water to return as sheet flow back into the ground, and minimize the potential for test water to reach Spencer Creek as described in the *Hydrostatic Test Plan* (appendix U). Additionally, various water treatment methods would be used to disinfect water that would be transferred across water basin boundaries including screening/filtering, chlorine treatment, and discharge to upland sites to prevent the potential spread of aquatic invasives (see appendix U).

3.4.5.4 Conservation Measures

Conservation measures have been proposed by PCGP to minimize construction and operation impacts to waterbodies and riparian zones. Those measures have been compiled in table 2C in appendix N and would apply to Oregon spotted frogs.

3.4.5.5 Determination of Effects

Species

The Project **may affect** Oregon spotted frogs because:

- the Pipeline would cross Spencer Creek, which is hydrologically connected to Buck Lake and is occupied by the Oregon spotted frog; and
- the Pipeline is within 280 feet of Spencer Creek and crosses tributaries to Spencer Creek downstream of Buck Lake, which is occupied by the Oregon spotted frog.

However, the Project **is not likely to adversely affect** Oregon spotted frogs for the following reasons:

- Buck Lake is approximately 6,400 feet downstream from where the Pipeline would cross Spencer Creek. Suspended sediment generated by construction is expected to remain in the water column for up to 1,450 feet downstream from the construction site. Suspended sediment in Spencer Creek would pass through Buck Marsh but Oregon spotted frogs do not currently inhabit Buck Marsh.
- If the Oregon spotted frog does occur in Buck Marsh at the time of construction, conservation measures would limit potential effects due to acoustic shock,

introduction of non-native species and/or disease, fuel and chemical spills, and herbicides. Future presence of Oregon spotted frogs in the Spencer Creek upstream of Buck Lake at the time of construction is extremely unlikely, and is considered to be discountable.

- Although the right-of-way occurs as close as 280 feet from Spencer Creek downstream of Buck Lake, the right-of-way and Spencer Creek are separated by Clover Creek Road and are not hydrologically connected; BMPs and erosion control measures should prevent sediment from the construction right-of-way from entering Spencer Creek.
- Effects on Oregon spotted frogs from hydrostatic discharge are insignificant and discountable because the nearest hydrostatic discharge site is approximately 2.38 miles (straight-line distance) from designated critical habitat in Buck Lake. BMPs would prevent adverse effects from sedimentation or introduction of non-native species and disease, and a spill of hydrostatic test water is highly unlikely.

Critical Habitat

The Project **may affect** proposed critical habitat for the Oregon spotted frog because:

- the Pipeline is within 280 feet of proposed critical habitat within Spencer Creek downstream of Buck Lake; and

However, the Project would **not adversely modify** designated critical habitat for the Oregon spotted frog because:

- the designated critical habitat within 280 feet of the right-of-way is not hydrologically connected to the right-of-way; and
- test water from the proposed hydrostatic discharge site at MP 169.52 is not expected to reach the proposed critical habitat in Spencer Creek or Buck Lake, so effects to PCEs from changes in hydrology or introduction of nonnative species from the Project are discountable.

The Pipeline **may affect, but is not likely to adversely affect** critical habitat Unit 14 for the Oregon spotted frog.

3.5 FISH

3.5.1 North American Green Sturgeon (Southern Distinct Population Segment)

3.5.1.1 Species Account and Critical Habitat

Status

On January 29, 2003 (NMFS 2003), NMFS determined that the North American Green Sturgeon comprises two Distinct Population Segments (DPSs) that qualify as species under the ESA: 1) a northern DPS consisting of populations in coastal watersheds northward of and including the Eel River in California; and 2) a southern DPS consisting of coastal and Central Valley populations south of the Eel River, with the only known spawning population in the Sacramento River. At that time however, neither DPS was listed because of the uncertainty about the population structure and status.

In April 2006, NMFS listed the Southern DPS as threatened under ESA within California, including spawning population of green sturgeon south of the Eel River, principally the Sacramento River green sturgeon spawning population (NMFS 2006c). The Pacific Northern DPS, which includes coastal spawning populations from the Eel River north to the Klamath and Rogue Rivers, remains unlisted but is a Species of Concern (NMFS 2007c, 2014d). NMFS performed a five-year status review in 2015, wihich determined that no change in status was needed for the Southern DPS (NMFS 2015c).

Threats

The southern DPS was proposed for listing as threatened in 2005 (NMFS 2005b) because 1) the majority of spawning adults were concentrated in one spawning river (Sacramento River), 2) threats since the first status review (see NMFS 2002) have not been adequately addressed, 3) new evidence of loss of spawning habitat in the upper Sacramento and Feather Rivers, and 4) data showing a negative trend in juvenile green sturgeon abundance. One factor that was not considered a primary factor causing the decline of the Southern DPS, but likely poses a threat to the Southern DPS, was past and present commercial and recreational fishing, primarily ocean and estuarine bycatch of green sturgeon in the Oregon and Washington white sturgeon and salmonid fisheries; however, recent fishing regulations have reduced the risk for Southern DPS in Oregon and Washington (NMFS 2006c). Actions that may negatively affect the Southern green sturgeon DPS include water diversion for human use, point and non-point source discharge of persistent contaminants, contaminated waste disposal, water quality standards, and fishery management practices (NMFS 2006c).

The principal threat to the southern DPS green sturgeon remains as limited spawning habitat in the Sacramento River, California. Multiple dams on the river prevent adult migration to former spawning sites. Also, flow rates in the river and Delta have been affected by water diversions for agricultural, municipal and industrial uses, and insufficient flow rates in the Sacramento River system are likely a significant threat to green sturgeon (NMFS 2006c). In particular, entrainment of juveniles in water diversion structures has been identified though may not be as much as a problem as thought earlier (NMFS 2005b). Other adverse effects within the Sacramento River system include elevated water temperatures and contamination from toxic materials (e.g., bioaccumulation of PCBs and selenium).

Species Recovery

No recovery plan has been drafted.

Life History, Habitat Requirements, and Distribution

Green sturgeons spawn in deep pools in large, turbulent river mainstems, generally from March through July with peak spawning from mid-April to mid-June (Moyle 2002). Adults migrate to/from spawning grounds during the spring and fall, consecutively, and juvenile migration occurs from April through November (Rien et al. 2001). Northern DPS green sturgeons enter the Rogue River during March through June to spawn. Spawning appears to be related to water temperature (8.8º to 16.4ºC or 48º to 62ºF) but low flows probably dictate how far upstream sturgeon are able to migrate to potential spawning habitat (Erickson and Webb 2007).

Little is known about sturgeon feeding, but some studies have found that adults and juveniles feed on benthic invertebrates including shrimp, mollusks, amphipods, and even small fish

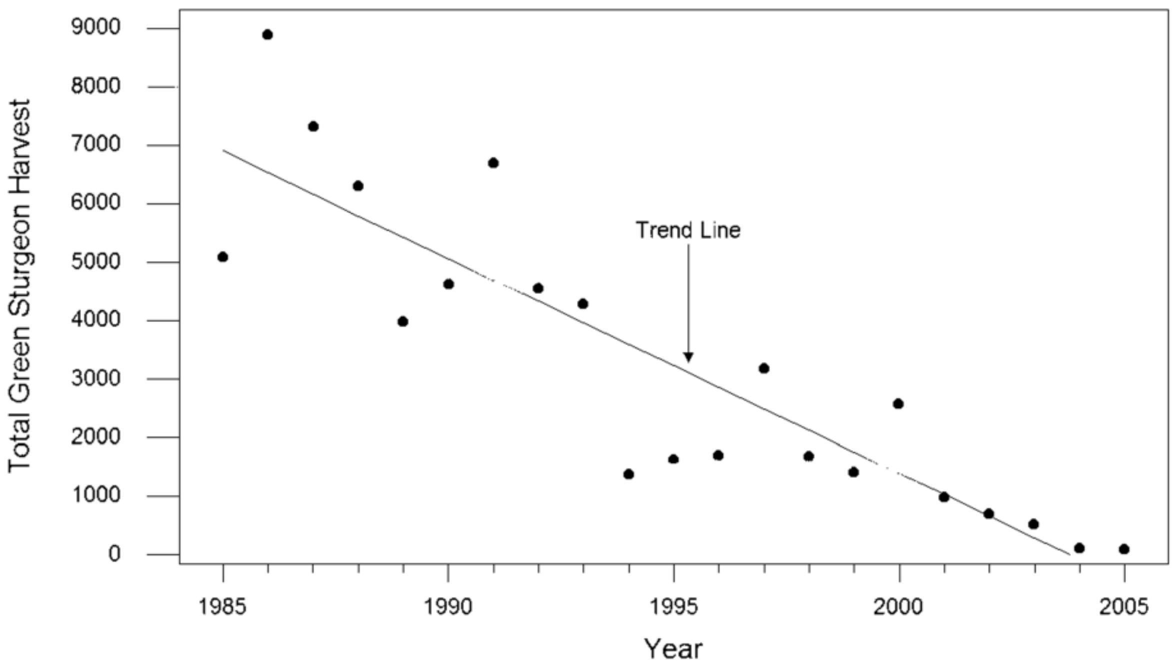
(Moyle 2002). They are thought to spend most of their lives in nearshore oceanic waters, bays, and estuaries (NMFS 2014d).

Green sturgeon move into estuaries of non-natal rivers to feed (Beamis and Kynard 1997). They occupy large estuaries during the summer and early fall in the Pacific Northwest. Green sturgeons enter Washington estuaries during summer when water temperatures are more than 4ºF warmer than adjacent coastal waters (Moser and Lindley 2007). Green sturgeon abundance peaks during October in the Columbia River estuary, based on commercial catches. In Washington (Willapa Bay and Grays Harbor), green sturgeons appear to be present from June until October (Moser and Lindley 2007). Sturgeons in the Southern DPS that originate in the Sacramento River have been found widely in Washington estuaries and the Columbia River. In the lower Columbia River (river mile 0 to 35), between 77 and 88 percent of the green sturgeons collected originated from the Southern DPS (Israel and May 2007).

Data from tagged green sturgeons occurring offshore from the Klamath River in California suggests they are from the northern and southern DPS. Tagged green sturgeons that utilize the lower Klamath River have been observed in Grays Harbor, Washington (McCovey 2007), approximately 400 nmi north of the Klamath River. There are no records of tagged green sturgeon occurring within Coos Bay which is approximately 125 nmi from the Klamath River estuary.

Population Status

It has been reported that there are no good data on current population of the green sturgeon (NMFS 2014d). ODFW evaluated the presence of green sturgeon in coastal tributaries through 2005 and provided summaries of harvests of green sturgeon in California, Oregon, and Washington commercial and sport fisheries (Farr and Kern 2005). Although many factors contribute to annual catch of sturgeons in the three states whether in coastal, estuarine, or riverine habitats, the overall declining trend since 1985 (see figure 3.5.1-1) is probably indicative of the species' declining population.



Source: Farr and Kern 2005

Figure 3.5.1-1 Total Harvest of Green Sturgeon in California, Oregon, and Washington Commercial and Sport Fisheries from 1985 to 2005. The linear relationship is significant (r^2 = 0.786, P<0.001).

There are confirmed records of green sturgeon in the Umpqua River, captured above the zone of tidal influences. In 2000, two juvenile green sturgeons were regurgitated from a smallmouth bass caught in the Umpqua River (river kilometer 134 [RM 83.3]), and in 1979, a green sturgeon nearly 2 meters (6.6 feet) long was caught at river kilometer 164 (RM 101.9; NMFS 2005b). In addition, a possible juvenile green sturgeon was captured at Big Butte Creek, near Lost Creek Dam on the Rogue River (NMFS 2005b). From 2000 to 2004, 249 green sturgeons were captured in the Rogue River, while 33 fish were captured and 2 sturgeons that had been tagged were recaptured in the Umpqua River (Farr and Kern 2005). However, there is no indication to which DPS any of those reported green sturgeons belonged.

Critical Habitat

During reviews prior to designating critical habitat, NMFS (2008b) determined that subadult and adult Southern DPS green sturgeon inhabited certain estuaries along the coast of northern California, Oregon, and Washington during summer and inhabited coastal marine waters from central California to British Columbia over the winter. NMFS (2008b) noted large numbers of adult and subadult green sturgeons used Coos Bay as summer habitat, in particular Southern DPS green sturgeons tagged in San Pablo Bay, a northern extension of San Francisco Bay. Based on that information, NMFS (2009b) designated critical habitat for the Southern DPS of North American green sturgeon to include all tidally influenced areas of Coos Bay up to the elevation of mean higher high water, including the head of tide endpoint in the Coos River and Stock Slough both of which are crossed by the Pipeline. The Pipeline would cross Stock Slough approximately 220 feet upstream from the head of tide endpoint for critical habitat in Stock Slough.

PCEs have been identified for critical habitats including: 1) freshwater riverine systems, 2) estuarine habitats, and 3) nearshore coastal marine area. The fresh water riverine component includes the Upper and Lower Sacramento River, Lower Feather River, Lower Yuba River, and several bypasses in the Sacramento-San Joaquin Delta, all of which are in California.

Coos River and Stock Slough are identified as freshwater river habitat components of designated critical habitat although no spawning has been documented in either. Likewise, green sturgeon early life stages are within freshwater and affected by water flow and temperature, but post-larval juvenile sturgeons are not expected in the Coos River or Stock Slough because there are no spawning sites. Nevertheless, the Pipeline has some potential to affect some PCEs essential for the conservation of the Southern DPS in freshwater riverine systems which include:

1. Food resources. Abundant prey items for larval, juvenile, subadult, and adult life stages.
2. Substrate type or size. Substrates suitable for egg deposition and development, larval development, and subadults and adults.
3. Water flow. A flow regime (magnitude, frequency, duration, seasonality, and rate-of-change of fresh water discharge over time) necessary for normal behavior, growth, and survival of all life stages.
4. Water quality. Water quality, including temperature, salinity, oxygen content, and other chemical characteristics, necessary for normal behavior, growth, and viability of all life stages.
5. Migratory corridor. A migratory pathway necessary for the safe and timely passage of Southern DPS fish within riverine habitats and between riverine and estuarine habitats.
6. Water depth. Deep (≥5 m) holding pools for both upstream and downstream holding of adult or subadult fish, with adequate water quality and flow to maintain the physiological needs of the holding adult or subadult fish.
7. Sediment quality. Sediment quality (i.e., chemical characteristics) necessary for normal behavior, growth, and viability of all life stages.

All of the riverine PCEs, except for PCE 2, are expected within the riverine analysis area (described below).

The Pipeline project has the potential to affect estuarine PCEs within Coos Bay and coastal tributaries when occupied by subadult and adult green sturgeon (NMFS 2009c). NMFS (2008b) determined that the Coos Bay estuary provided food resources, water flow, water quality, and migratory corridors to support migration and possibly feeding by subadult and adult green sturgeon. Estuarine PCEs include:

1. Food resources. Abundant prey items within estuarine habitats and substrates for juvenile, subadult, and adult life stages.
2. Water flow. Within bays and estuaries adjacent to the Sacramento River (i.e., the Sacramento-San Joaquin Delta and the Suisun, San Pablo, and San Francisco bays), sufficient flow into the bay and estuary to allow adults to successfully orient to the incoming flow and migrate upstream to spawning grounds.
3. Water quality. Water quality, including temperature, salinity, oxygen content, and other chemical characteristics, necessary for normal behavior, growth, and viability of all life stages.

4. Migratory corridor. A migratory pathway necessary for the safe and timely passage of Southern DPS fish within estuarine habitats and between estuarine and riverine or marine habitats.
5. Depth. A diversity of depths necessary for shelter, foraging, and migration of juvenile, subadult, and adult life stages.
6. Sediment quality. Sediment quality (i.e., chemical characteristics) necessary for normal behavior, growth, and viability of all life stages.

NMFS (2009c) identified coastal marine water depths within 110 meters (360 feet) as occupied areas necessary to critical habitat, including coastal waters segments from San Francisco Bay to Humboldt Bay, California and from Humboldt Bay to Coos Bay. Migratory corridors, water quality and food resources are PCEs associated with coastal marine habitat components of critical habitat (NMFS 2009c).

The specific PCEs in coastal marine areas include:

1. a migratory pathway necessary for the safe and timely passage of Southern DPS fish within marine and between estuarine and marine habitats without human-induced impediments, either physical, chemical, or biological, that would affect the migratory behavior of the fish such that its survival or the overall viability of the species is compromised;
2. coastal marine waters with adequate dissolved oxygen levels and acceptably low levels of contaminants (e.g., pesticides, PAH heavy metals that may disrupt the normal behavior, growth, and viability of subadult and adult green sturgeon); and
3. abundant prey items for subadults and adults, which may include benthic invertebrates and fish.

3.5.1.2 Environmental Baseline

Analysis Area

Three analysis areas within the overall action area are applicable to green sturgeons in the Southern DPS: the marine analysis area, the estuarine analysis area, and the riverine analysis area. The marine analysis area is a fan-shaped area spreading outward from the Coos Bay entrance to the outer continental shelf, which extends approximately 12 nmi offshore. Within the marine analysis area, LNG vessel traffic may have effects on green sturgeons within coastal marine waters up to 110 meters (about 360 feet) deep. This accounts for approximately half of the marine analysis area, or out to 7.5 nmi from the Coos Bay entrance. The LNG carriers are assumed to transect the marine analysis area mostly perpendicularly (east and west as they approach and depart from Coos Bay (see the discussion in section 3.2.1.3 for blue whales).

The Coos Bay estuarine analysis area includes: 1) the existing Federal Navigation Channel which forms part of the waterway for LNG carrier traffic to and from the LNG Terminal, 2) the proposed access channel to the terminal slip, 3) the Navigation Reliability Improvements, 4) the area of North Slough adjacent to the Trans Pacific Parkway/U.S. Highway 101 (US-101) Intersection Widening, 5) the Eelgrass Mitigation site, 6) the Kentuck Project site, and 7) sites temporarily occupied during construction activities (see figure 2.1.1-2 under section 2.1.1, Jordan Cove Energy Project Component Description and figure 3.3.3-3 under section 3.3.3, Marbled Murrelet).

The riverine analysis area includes accessible freshwater tributaries to Coos Bay that would be crossed or potentially affected by construction of the Pipeline below the head-of-tide influence with potential use by green sturgeon.

Species Presence

It is likely that the North American green sturgeon (both the unlisted Northern DPS and threatened Southern DPS) occur within Coos Bay and its adjacent waterbodies, such as the Coos River. Green sturgeon have been taken in almost all of the Oregon coastal estuaries from the Chetco River to Nehalem Bay (EPIC et al. 2001) and genetic studies indicate that both Northern DPS and Southern DPS occur in the Columbia River (Israel et al. 2004).

There are historical records of green sturgeons caught in the Coos Bay commercial fishery (ranging from 67 to nearly 2,000 pounds of fish annually) between 1923 and 1949. Furthermore, ODFW has records of green sturgeon caught off Cooson Point, Hays Slough, at the confluence of the Millicoma and Coos Rivers, in Davis Slough, and South Coos River (Farr and Kern 2005). If their presence in Coos Bay is similar to occurrences on other large estuaries in Oregon and Washington, including the Columbia River, Willapa Bay and Grays Harbor, then a relatively high proportion of green sturgeons may be from the Southern DPS, perhaps as high as 77 to 88 percent, similar to occurrence in the lower Columbia River (Israel and May 2007).

Green sturgeon movements within the 100-meter (328-foot) isobath during migration along the West Coast were monitored using pinger-tags and hydrophone arrays. Although data are limited, tagged sturgeons moved from Seal Rock, Lincoln County, on the Oregon coast north of Coos Bay, south to Monterey Bay, California at the rate of 2 kilometers (1.2 miles) per day and from Seal Rock north to Brooks Peninsula, B.C. at the rate of 4.2 kilometers (2.6 miles) per day (Lindley et al. 2008). Migrating green sturgeons were documented along the Oregon coast (Seal Rock) mostly between October and June (Lindley et al. 2008).

Habitat

Coos Bay is known to support a small population of green sturgeon; however, natural reproduction in the estuary is considered low (Wagoner et al. 1990). The Coos River system is not considered to provide suitable spawning habitat for green sturgeon (Whisler et al. 1999). However, historical records of the American shad gill-net fishery in the Isthmus Slough indicate that green sturgeon were incidentally captured nearly every year from 1980 to 1992 (Farr and Rien 2002). ODFW reported that many of these fish were probably younger than three years old based on their size and suggested that the Coos Bay system may provide spawning or at least rearing habitat for juveniles (Cummings and Schwartz 1971; ODFW 2006b). Green sturgeons may utilize both shallow and deep water habitats within the estuarine analysis area though there is no information relating individuals' occurrence to DPS membership.

Coastal bays and estuaries provide habitats that support juvenile rearing and growth through the time when they enter coastal marine habitats (NMFS 2009c). Since no spawning occurs in freshwater tributaries to Coos Bay, the estuary most likely provides feeding and migratory habitat for adult and possibly subadult green sturgeons. Based on food habit studies in several Washington estuaries, adult and subadult green sturgeon fed on a variety of invertebrates such as crangonid shrimp, burrowing thalassinidean shrimp, burrowing ghost shrimp (*Neotrypaea californiensis*) and possibly other related species, amphipods, clams, and juvenile Dungeness crab (*Metacarcinus magister*) as well as vertebrates including anchovies, sand lance (*Ammodytes hexapterus*), lingcod (*Ophiodon elongatus*), and other fish (NMFS 2009c).

Presence of potential forage species within the vicinity of the Federal Navigation Channel (Miller et al. 1990) is discussed below for Oregon Coast coho salmon (see section 3.5.4). Total benthic invertebrate densities in Coos Bay were found to be lower than densities observed in the Umpqua River Estuary and the Columbia River Estuary (Bottom et al. 1985; Miller et al. 1989; Durkin and Emmett 1980). Benthic studies conducted by NMFS within and in the vicinity of Coos Bay found that the amphipod, *Corophium salmonis*, occurred in much lower densities than in other Oregon estuaries (Miller et al. 1990; Bottom et al. 1985; Miller et al. 1989; Durkin and Emmett 1980). Previous studies in Coos Bay have found that *Corophium* spp. were abundant in intertidal areas and constituted an important diet element for juvenile Chinook salmon and striped bass (BLM 1971).

Green sturgeons utilize West Coast estuaries during summer months when estuarine water temperatures exceed ocean coastal temperatures, perhaps optimizing their growth potentials by foraging in relatively warm, saline estuarine water (Moser and Lindley 2007). The Oregon Department of Environmental Quality (ODEQ) periodically monitored water temperatures in Coos Bay at Marker #23 (near Henderson Marsh) from 1957 to 2005 (ODEQ 2006), located just downstream from the Project site. Although the data are not continuous, they provide a general range of water temperatures in close proximity to the Project site. Temperatures collected during the period of record ranged from 5°C to 13°C (41°F to 55°F) in the winter to 9°C to 20°C (48°F to 68°F) in the summer (ODEQ 2006).

Dissolved oxygen (DO) in lower Coos Bay is generally higher in the winter and lower in the summer. During winter, DO ranged from 8.9 to 10.4 mg/l and averaged 9.4 mg/l. During summer, DO ranged from 6.0 to 9.6 mg/l and averaged 7.4 mg/l (ODEQ 2006). Arneson (1976) also sampled DO in the bay and reported that DO concentrations were slightly higher in December and March than in June and September. Lower DO levels in the summer are associated with lower freshwater inputs but would be a “properly functioning” habitat indicator, overall.

Critical Habitat

NMFS (2009c) designated critical habitat for the Southern DPS of North American green sturgeon to include all tidally influenced areas of Coos Bay up to the elevation of mean higher high water, including the head of tide endpoints in the Coos River and Stock Slough, both of which are crossed by the Pipeline.

The Coos Bay estuary provides several PCEs including food resources, migratory corridors (passage) between estuarine and marine habitats, sediment quality and water quality (NMFS 2009c), all necessary to support various green sturgeon life stages. Similarly, coastal marine waters between Coos Bay and San Francisco Bay provide food, passage, and water quality as PCEs.

NMFS (2008b) determined that the Coos Bay estuary provided food resources, water flow, water quality, and migratory corridors to support migration and possibly feeding by subadult and adult green sturgeon. Shallow water habitats near the Project site have been mapped as habitat for *Corophium* spp. by Coos County Planning Department (1979). Ghost shrimp more commonly inhabit tide flats closer to the ocean and in Coos Bay; ghost shrimp may be further inland because of predation by the Pacific staghorn sculpin (Hornig et al. 1989; Posey 1986). Those species as well as bivalve mollusks (softshell, butter, littleneck, cockle, gaper piddocks and mussels) may provide food for migratory green sturgeon within the estuarine and near-shore marine analysis areas.

Lower Coos Bay provides unobstructed migratory access for juvenile and adult salmonids, discussed above, and similarly assumed to be unobstructed for green sturgeons. Within the estuarine analysis area and lower riverine analysis area entering Coos Bay, access for migrating fish species is uninhibited, and is therefore considered "properly functioning."

3.5.1.3 Effects of the Proposed Action

Analyses of effects for green sturgeon are addressed separately for the marine analysis area, estuarine analysis area, and riverine analysis area.

Direct and Indirect Effects – Marine Analysis Area

Potential project-related effects to the Southern DPS of green sturgeon within the marine analysis area include the following : 1) acoustic effects to sturgeon from LNG carriers transiting the marine analysis area, and 2) oil, gas, and fuel spills from LNG carriers at sea.

Acoustic Effects

Underwater noise produced by LNG carriers transiting the marine analysis area may affect green sturgeon. Underwater noise levels are expected to vary by ship type and also by vessel length, gross tonnage, vessel speed, and to some extent, vessel age—older vessels tend to be louder than newer vessels (see discussion in section 3.2.1.3 for blue whales). Based on the general trend for higher underwater noise generated by larger vessels (McKenna et al. 2012), it is possible for some of the LNG carriers that would utilize the LNG Terminal to generate more noise than the LNG carriers built in 2003 with 138,028 m^3 capacity reported by Hatch et al. (2008) that produced sound levels (with 1 standard error) of 182 ± 2 dB re: 1 µPa @ 1 meter.

State agencies in Washington, Oregon, and California along with federal agencies have developed interim noise exposure threshold criteria for pile-driving effects on fish (WSDOT 2011a; Fisheries Hydroacoustic Working Group 2008; Popper et al. 2006). These threshold criteria are considered levels below which injury effects would not occur to fish from in water noise. These thresholds should be thus suitable for all forms of in-water noise. Interim noise exposure threshold criteria for pile driving effects on fish include: 1) a cumulative sound exposure level (SEL_{cum}) of 187 dB re 1 μPa^2 s for fishes weighing more than two grams, 2) a SEL_{cum} of 183 dB re 1 μPa^2 s for fishes less than two grams, and 3) a single-strike peak level (SPL_{peak}) of 206 dB re 1 µPa for all sizes of fishes (WSDOT 2011a). The LNG carrier in the Hatch et al. (2008) study produced sound levels (with one standard error) of 182 ± 2 dB re: 1 µPa @ 1 meter that attenuated to 160 dB at 35 ± 11 meters and to 120 dB at 16,185 ± 5,359 meters (Hatch et al. 2008).

All project vessel noise values generated in the marine analysis area would be less than those noted above as causing direct harm to fish, with the possible exception for very small fish within 1 meter (3 feet) of an LNG carrier hull for an extended period. Green sturgeon are generally epibenthic and would rarely be in the near surface waters. Additionally, since vessels are in transit, fish can easily move away from vessels, which would keep their exposure very brief and further reduce the chance for harmful exposure to sound and the potential for adverse noise effects.

Noise from LNG vessels would likely increase the background noise within the marine analysis area, While the background levels are not specifically known in the marine analysis area, analyses of more recent vessel-traffic related noise show that levels along the U.S. west coast area holding steady or increasing slightly off Southern California but decreasing in the area off Oregon and Washingon (Andrew et al. 2011). As noted above, green sturgeon in the marine analysis area might detect noise from LNG vessels but are not expected to be adversely affected.

Fuel or Oil Spills at Sea

The LNG carriers use either a steam or dual fuel diesel electric propulsion system that is primarily fueled by natural boil-off gas. Fuel (e.g., diesel) used for back-up generation for LNG carrier propulsion and oil or hydraulic fluids used for mechanical equipment could possibly leak or be spilled while the carriers are in transit. The low volumes of petroleum oils and fuel on LNG carriers greatly reduces the risk of impacts in the marine environment or on green sturgeon from petroleum spills. The Federal Water Pollution Control Act, as amended by the CWA (33 U.S.C. 1251–1387), prohibits the discharge of oil upon the navigable waters of the U.S., which include. Also, LNG carriers calling on the LNG Terminal would be required by the Coast Guard to have a vessel response plan in order to be adequately prepared for accidental spills, as described in section 3.2.1.4 for blue whales. As reported by Pacific States/British Columbia annual reports (2002), the number of oil spills reported from fishing, recreational and other harbor marine vessels in Oregon ranged from about 9 to 65 per year, which is fairly infrequent considering that thousands of marine vessels, both recreational and commercial, utilize Oregon coastal marine waters. Therefore, neither fuel nor oil leaks from LNG carriers transiting in the waterway to and from the LNG Terminal are likely to have adverse effects on aquatic resources including green sturgeon.

Direct and Indirect Effects – Estuarine Analysis Area

A summary of marine and estuarine habitat areas temporarily and permanently affected by construction and operation of the LNG Terminal is presented in tables 2.3-1 and 2.3-2 in JCEP's Resource Report 2. Potential project-related effects to the Southern DPS of green sturgeon within the estuarine analysis area are summarized below:

a. Timing of construction activities to life history functions;
b. Turbidity from capital related to the Terminal slip entrance, access channel, and Navigation Reliability Improvements, and the Eelgrass Mitigation Site;
c. Contamination from dredging;
d. Suspended sediment potentially released during HDD construction across Coos Bay Estuary and Coos River;
e. Turbidity from LNG carrier propeller wash and ship wakes;
f. Erosion and runoff;
g. Stormwater discharge at the LNG Terminal;
h. Stranding of juvenile sturgeons by LNG carrier ship wake;
i. Introduction of exotic, invasive species from ballast water exchange;
j. Entrainment during dredging activities;

k. Entrainment and impingement of juvenile sturgeons and prey species at engine cooling water intake portals of LNG carriers while at berth;
l. Effects from changes in temperature;
m. Lighting systems associated with construction and operation;
n. Noise from capital and other in-water construction;
o. Effects to habitat; and
p. Shading the water surface by construction of overwater structures.

Timing to Life History Functions

In-water construction of the JCEP Project within the Coos Bay estuary is planned from October 1 through February 15 following ODFW's recommendation. Because spawning is undocumented in freshwater tributaries to Coos Bay, the estuary most likely supports adult and possibly subadult green sturgeons by providing feeding and migratory habitat. In other watersheds where tributaries support spawning, adults migrate to/from spawning grounds during the spring and fall, consecutively, and juvenile migration occurs from April through November (Rien et al. 2001). Green sturgeon move into estuaries of non-natal rivers to feed (Beamis and Kynard 1997) and occupy large estuaries during the summer and early fall in the Pacific Northwest. Green sturgeon abundance peaks during October in the Columbia River estuary, but the same may not be true of green sturgeon abundance in Coos Bay. Nevertheless, the Southern DPS of green sturgeon could be present within the estuary coincidental with in-water construction for the Project.

Turbidity Effects from Dredging in Coos Bay

Resuspension of sediments and temporary increases in turbidity above Coos Bay background levels would occur while installing and removing the temporary earthen berm at the LNG Terminal slip and while dredging the access channel and Navigation Reliability Improvement sites. Construction of the LNG Terminal slip would require the excavation and dredging of Coos Bay shoreline near Jordan Cove, including removal of about 5.7 mcy of sediment as part of the development of a slip and access channel. The 5.7 mcy of materials would be used to raise the elevation of the LNG Terminal and the South Dunes site to elevations above the tsunami inundation zone.

At least 3.6 mcy at the slip would be removed behind a berm in an upland area separated from the bay, with little potential for sediments to affect the marine environment. The remaining 2.1 mcy would be removed by dredging of the berm (0.7 mcy) and the new access channel (1.4 mcy) in the bay. The access channel would be dredged to a depth of minus 45 feet (NAVD88).

Turbidity was modeled for the capital (i.e., new construction) dredging operations based on the anticipated geotechnical and environmental conditions for this project using the COE's DREDGE model and two dimensional numerical model Mike21 (Moffat & Nichol 2006, 2017a). Modeling results and additional information provided the basis for characterizing effects from turbidity generated by the various JCEP dredging activities.

Dredging of the access channel would result in elevated suspended sediment and turbidity levels in a localized area for a short time period. The time frame over which turbidity plumes would dissipate, from the point of dredging, is anticipated to be on the order or minutes to less than an hour in areas of higher tidal currents due to dilution and spreading. When dredging the Access Channel directly adjacent of the FNC, the turbidity plume is expected to become more elongated as the dredging becomes more proximate to the main channel flow. Modelling demonstrated the maximum extent of the turbidity plume, defined by the simulated 10 nephalometric turbidity units (NTUs) above background contour, to be approximately 780 and 750 feet when using cutter suction and clamshell dredges, respectively. (Moffatt & Nichol 2017a). Construction of the Access Channel and removal of the berm at the Slip would require a total volume of 1.9 million cubic yards (mcy) of material from saltwater dredging using a combination of cutter suction and clamshell dredge methods. This would require about four to six months to complete over three in-water work windows (October 1 to February 15). Turbidity is expected to dissipate to background levels within a few hours after dredge operations cease.(Moffatt & Nichol 2017a).

On average, the COE removes approximately 550,000 cy from the bar, 200,000 cy from CM 2 to 12, and 150,000 cy from CM 12 to 15 each year. The COE claims that its maintenance dredging of the Federal Navigation Channel does not significantly increase turbidity below CM 12 (Roye 1979).

For the Navigation Reliability Improvement sites, a total of approximately 584,300 cy of dredge material would be removed from four locations (referred to as Dredge Areas 1 through 4) adjacent to the existing Federal Navigation Channel between RM 2 and 7. These areas would be dredged to a controlled depth to match the adjacent Federal Navigation Channel, which is currently -37 feet MLLW. Dredging is expected to require about 5 months to complete, with an additional 45-day mobilization period, based on an assumed production rate of 7,700 cy per day and could be spread over four in-water work windows. Extending this in-water work over four construction seasons also would improve the logistical feasibility of material placement at APCO Site 2.

Dredging methods would be similar to what is described above for the slip and access channel and could include mechanical methods from a barge or hydraulic cutter section dredging. Material from the four dredge areas would be moved to the APCO Sites. The potential turbidity plume extents, defined by the simulated 10 NTU above background contour, from the Navigation Reliability Improvements varies by location and dredge equipment but could extend from 2,820 feet to 4,600 feet from the activity for a short period depending on the ebb and flow of the tidal current and extent of additional sediment generated (Moffatt & Nichol 2017c).

Aquatic organisms in Coos Bay are adapted to periods of high to moderate TSS (measured as turbidity) during winter months. Dredge operations are expected to result in exposure to similar levels of TSS, with higher concentrations expected in the immediate area of dredging. Ambient background levels of TSS in water are created by flows, waves and ship traffic. Within Coos Bay, ambient turbidity levels have been assessed based on several studies. As described by Moffatt & Nichol (2006), the average concentration of TSS measured near the proposed LNG terminal site was 14 mg/l with a range of 0-25 mg/l. This report also references a longer record of Coos Bay background data reported by NOAA for the period of April 2002 to December 2004 at the Charleston Bridge station located closer to the bay entrance than the LNG terminal site. Based on results from this study, the average summer and winter TSS levels at the Charleston Bridge station were 10.1 and 27.3 mg/l, respectively, which are equivalent to 5.8 and 12.2 NTUs.

More recently, hourly turbidity readings taken at the North Spit-BLM boat ramp gauge were compiled between August 2013 and January 2015. Preliminary data processing was first conducted to remove high turbidity measurements obtained over extended periods of time, as these typically occurred when dredging activities were ongoing. In addition, based on an empirical relationship developed for nine streams in the Pacific Northwest, turbidity values expressed in NTUs were converted to TSS in mg/L. Based on these data, the average natural turbidity level was calculated to be 40 mg/L at the North Spit-BLM boat ramp gauge (Moffatt &Nichol 2016).

At the Eelgrass Mitigation Site, a total of 40,000 cy of dredge material will be removed most likely with a small hydraulic dredge. Modeled turbidity values were determined to range from 270 to 290 NTUs. The potential turbidity plume extent, defined by the simulated 10 NTU above background contour, from the excavator dredge area would be generally limited to between 340 and 360 feet in all directions (Moffatt &Nichol 2017c). Since the site is a more confined and shallow area with somewhat limited circulation, the turbidity plume would be maintained within the local area of excavation. The duration of suspended sediment settling, therefore, is expected to be very short with turbidity dissipating to background levels within an hour after dredge operations cease, depending on the tidal cycle.

As indicated in Section 3.1.6 of the DMMP and Section 4 of the 10-17-17 Eelgrass Dredging/Excavation Means and Methods Feasibility Technical Memo, the design approach for dredging and turbidity management at the eelgrass mitigation site would involve:

- a hydraulic dredge pump system mounted on a long-reach excavator;
- a 3,900 foot long, 14-inch diameter, steel or anchored HDPE material transport pipeline;
- two booster pumps mounted on small anchored/spudded barges (or on small temporary platforms secured by 3-4 support piles);
- a loader operating on a 60-foot by 200-foot deck barge stationed near the FNC in about 20 feet of water;
- several 10 to 24-inch diameter moorage pile for stationing the deck barge;
- and scows and/or barges equipped with containment berms to accommodate hydraulic loading and settling of dredge material

The containment system on the scows and/or barges will minimize the release of turbid decant water back into the bay. If determined feasible, silt curtains at the dredge site also could be deployed to limit the dispersion of turbid waters to the local embayment as the bathymetry is modified to make it more suitable for eelgrass transplants the following year. As described in Section 4.2.2.1 of the APDBA, other operational controls would be employed to assure compliance with water quality criteria as stipulated in the Section 401 Certification issued by Oregon DEQ. As a result, effects to listed fish would be minimal.

If green sturgeon are exposed to moderate to high levels of suspended sediment for prolonged periods, adverse effects could occur to rearing fish. As noted, dredging is expected to create spikes of high to moderate turbidity in a localized area. Effects to green sturgeon are expected to be insignificant and discountable due to the limited area affected, the low likelihood of individual fish being present in the estuary, and limitations on construction periods. Based on these results, it is not anticipated that turbidity and suspended sediment generation at the dredging site would be a substantial issue.

Contamination Effects from Dredging

NMFS (2009c) has noted that subadults and adults feeding in bays and estuaries may be exposed to contaminants that may affect growth and reproduction. Such effects due to bioaccumulation of pesticides and other contaminants have been documented in white sturgeons that also inhabit West Coast estuaries (NMFS 2009c).

Sediments within the proposed dredge prism for the access channel were sampled to determine whether they meet Dredged Material Evaluation Framework (DMEF) guidelines, as identified for the Lower Columbia River Management Area, for in-water disposal (SHN 2006). An analysis of grain size distribution and total volatile solids composition was initially performed to determine if the sediments require further testing for chemical analysis. All of the samples were primarily composed of medium to fine grained sand and had a very low percentage of total volatile solids. Since none of the samples exceeded 20 percent fines or 5 percent total volatile solids, no further chemical testing was required and the sediments were deemed suitable for in-water disposal, according to DMEF guidelines. These findings indicate that resuspension of sediments associated with the dredging for the access channel should not result in significant increases in the bioavailability of contaminants to fish and fish food organisms within the analysis areas. Therefore, there is little to no risk of contamination as a result of dredging the access channel.

This conclusion is further supported by previous sediment evaluations conducted by the USACE in 2004 for Coos Bay channel maintenance and improvement dredging at various stations along the FNC (COE 2005). Throughout the entire sampling area, only low levels of sediment contaminants were identified, with all levels well below their respective DMEF screening levels. One of the sampling stations (0915CB-BC-10) was located approximately 0.4 mile downstream of the LNG Terminal. The 2004 sediment sampling effort found only low levels of chemical contaminants, with all levels below their respective DMEF screening levels. None of the samples contained dichlorodiphenyltrichloroethane (DDT) or its derivative by-products (dichlorodiphenly-dichloroethylene [DDE], dicholordiphenyldichloroethane [DDD]) at levels that could cause adverse effects to fish resources.

In 2011 and 2016, JCEP conducted geotechnical investigations at the NRI sites to support the JCEP's DMMP. Analysis of the physical characteristics of sediments at the NRI sites determined that sediment composition consisted of sand, silty sand, sandstone, and siltstone. This is similar to sediments collected from the adjacent FNC and from within the footprint of the proposed LNG Terminal access channel. These sediments were generally described as coarse-grained with high sand content, which the Portland Sediment Evaluation Team (PSET) previously determined suitable for unconfined aquatic disposal. Due to their proximity to previous sampling locations in the FNC and access channel, sediments to be dredged from the NRI sites will have a similar chemical character as will be confirmed based on future coordination with the PSET. Therefore, sediments at the NRI sites will also have a low likelihood of potential contaminants and will be suitable for unconfined aquatic disposal.

Turbidity Effects from Temporary In-water Construction

In-water construction activities are likely to temporarily increase TSS concentrations and turbidity. Such increases would result from in-water construction related to the:

- Temporary Material Barge Berth (TMBB),
- Material Offloading Facility (MOF),
- Trans Pacific Parkway/US-101 Intersection Widening,
- APCO Site access bridge construction,
- replacement of anchoring systems for existing meteorological ocean data collection buoys as well as addition of anchoring systems for two new buoys,
- establishment of hydraulic connections to the Kentuck Project for estuarine habitat mitigation, and
- creation of the Eelgrass Mitigation site.

Turbidity increases would be localized and limited to the time required to complete each of the respective JCEP Project components. Construction activities would occur within the ODFW in-water work window (October 1 to February 15). Effects to green sturgeon are expected to be insignificant and discountable due to the limited area affected, the low likelihood of individual fish being present in the estuary and limitations on construction periods. Based on these results, it is not anticipated that turbidity and suspended sediment generation at the construction site would be a substantial issue.

Suspended Sediment – HDD across Coos Bay Estuary and Coos River

Coos Bay would be crossed by two HDDs, one from MP 0.28 to MP 1.00 (West HDD), the other from MP 1.46 to MP 3.02 (East HDD). The Coos River (a tributary to the estuary) would also be crossed using HDD at MP 11.13. At that location, the Coos River is under tidal influence and is addressed here in the estuarine analysis area rather than in the riverine analysis area.

The horizontal crossing length of the West HDD would span 5,192 feet, extending from the North Spit to the southeast, crossing the Federal Navigation Channel and terminating at North Point in North Bend, Oregon. The HDD profile would pass approximately 158 feet below the railroad trestle bridge and approximately 138 feet below the deepest part of the Federal Navigation Channel. The depth and the locations of the railroad trestle foundations are unknown at this time (GeoEngineers 2017a). The feasibility analysis for the West HDD anticipates a relatively low risk of hydraulic fracture and drilling fluid surface releases occurring along most of the HDD alignment during construction. However, there would be a high risk of hydraulic fracture and drilling fluid surface release within about 150 feet of either end of the HDD due to the anticipated loose sand and decreased depth of cover. Installation of an oversized casing may be needed at both ends of the HDD path to assist in efficiently transferring axial loads to the drill bit, and to mitigate against hydraulic fracture and drilling fluid surface releases within the loose sand anticipated in the upper 30 feet (GeoEngineers 2017a).

The horizontal crossing length of the East HDD would span 8,972 feet extending from North Point in North Bend, Oregon eastward across Coos Bay and ending at the mouth of Kentuck Slough. Surface conditions at North Point at the west end of the HDD consist of a relatively flat ground surface covered with fill stockpiles. The east end of the HDD would be located within a flat grass vegetated area in Kentuck Slough Valley. The proposed depth of the Pipeline would be 210 feet below ground surface.

The alignment of the HDD would cross the Federal Navigation Channel and shallow tidal mud flats east of the Federal Navigation Channel. GeoEngineers (2017a) anticipates that the HDD would be completed using pilot hole intersect methods, due to the substantial length. Because this crossing would be completed using pilot hole intersect methods, both ends are identified as entry points. For this design, the carrier pipe would be strung and fabricated along the Kentuck Slough valley floor on the east end of the crossing. The proposed carrier pipe stringing area would be located northeast of the east entry point along the Kentuck Slough valley floor. Kentuck Slough and Kentuck Way limit the available pipe string length to 5,293 feet so a tie-in weld would be required during pullback operations. The orientation of the HDD alignment would require two horizontal curves in the pull section, making fabricating and handling the pipe more difficult.

Drilling fluid containment would be via relatively small fluid containment pits excavated adjacent to the entry points of the drill. These pits typically measure approximately 6 to 10 feet square and 4 to 6 feet deep. During drilling operations, drilling fluid returns and cuttings from downhole flow into the pits where the fluid is then pumped to a recycling system where most of the cuttings are removed and the drilling fluid can be recirculated downhole (GeoEngineers 2017a).

Because of the length of the HDD, there would be an increased risk of drilling fluid surface release during reaming operations. This risk can be reduced by reaming the hole from both ends of the crossing. This methodology helps reduce downhole annular drilling fluid pressures by shortening the flow path of the drilling fluid through the hole. Although this increased risk does not necessarily affect the technical feasibility of the proposed HDD, reaming from both sides of the crossing could potentially have cost impacts that may require consideration. In general, GeoEngineers (2017a) expects the risk of drill hole instability along the HDD drill paths to be relatively low.

According to GeoEngineers' design (2017b) for construction using HDD across the Coos River (see appendix E), the design length of the Coos River HDD crossing would be approximately 1,602 feet. The proposed entry point would be located approximately 500 feet from the north bank of the Coos River and the exit point would be approximately 630 feet from the south bank. The entry and exit points would allow for adequate depth beneath the Coos River. The preliminary design would provide a minimum of 50.3 feet of cover below the Coos River. GeoEngineers' evaluation determined that the construction of the Coos River HDD crossing is likely feasible. GeoEngineers opined that there is a relatively high risk of hydraulic fracture and drilling fluid surface releases along the first 500 feet and last 300 feet of the HDD, respectively. However, the risk of drilling fluid surface release to the Coos River would be relatively low. As is typical with all HDDs, the risk of drilling fluid surface release becomes high within approximately 150 feet of the exit. Drilling fluid surface releases may occur within these high risk zones even if the contractor maintains drilling fluid returns during construction and also maintains drilling fluid properties that are conducive to cuttings removal and formation of a "wall cake" to help stabilize the borehole and limit fluid interaction between the borehole and surrounding soils (GeoEngineers 2017b).

Inadvertent Release of Drilling Muds (Inadvertent Return)

The HDD installation method is considered an effective technique for avoiding in-stream impacts by eliminating the need for in-stream excavation (Reid and Anderson 1998; Reid et al. 2004). Even with this technique, there is a potential for impact as a result of the HDD process. Drilling requires use of a drilling mud for lubrication of the bit and removal of cuttings. A biodegradable bentonite clay mixture makes up drilling mud; bentonite is considered to be "practically non-toxic" (Reid and Anderson 1998). Because the drilling mud is under pressure during drilling, if the bit encounters substrate fractures or channels, it is possible for bentonite to escape from the hole (termed an "inadvertent return"). Bentonite can escape to the surface through fractures in the drilled substrate.

Bentonite by itself is generally considered a non-toxic drilling mud (Breteler et al. 1985; Hartman and Martin 1984; Sprague and Logan 1979), although according to Reid and Anderson (1998), the toxicity of bentonite (sodium montmorillonite) in fresh water ranges from 5,000 to 19,000 ppm (mg/liter) based on 96-hour tests for LC50 (the concentration at which 50 percent of the test population dies after 95 hours of exposure) on rainbow trout. The toxicity classifications based on LC50 values ranged from "slightly toxic" (5,000 ppm) to "practically non-toxic" (19,000 ppm) (Reid and Anderson, 1998). In other tests, toxicities to lake whitefish and rainbow trout demonstrated threshold concentrations of 16,613 and 49,838 ppm (mg/l), respectively (Reid and Anderson, 1998). LC50 concentrations >10,000 ppm would be considered "practically non-toxic". In marine water, a 96-hour LC50 bioassay for toxicity of bentonite on a mysid shrimp (*Mysidopsis bahia*) was >1,000,000 ppm (Reid and Anderson 1998).

Bentonite, as with any fine particulate material, can interfere with oxygen exchange by the gills of aquatic organisms (EPA 1986). The degree of interference generally increases with water temperature (Horkel and Pearson 1976). Impacts would be localized and would normally be limited to individual fish in the immediate vicinity of the inadvertent return. The majority of highly mobile aquatic organisms, such as fish, would be able to avoid or move away from turbidity spots and plumes (Reid and Anderson 1999). Other less mobile or immobile organisms, such as clams, mussels and other macroinvertebrates, would incur direct mortality (Wilbur and Clark 2001). Bentonite can smother macroinvertebrates and adversely affect filter-feeders (Falk and Lawrence 1973 in Hair et al. 2002 and Land 1974 in Cameron et al. 2002). Bentonite can also exacerbate or enhance the effects of toxic compounds to fish and aquatic invertebrates if those compounds are present in aquatic habitats (Hartman and Martin 1984). Similar to other fine-grained particulates, bentonite in flowing water is more likely to remain in suspension longer than in standing water. Consequently, effects to green sturgeon by a release of bentonite into a waterbody would ultimately depend on volume of the release, volume of water present, and current. Green sturgeon inhabiting larger waterbodies with swift currents would be less affected by a given volume of bentonite than those inhabiting small waterbodies with no current. Green sturgeon spawning would not occur within the estuarine or riverine analysis areas and larval sturgeons are not expected in either area.

Reid and Anderson (1998), the Canadian Pipeline Water Crossing Committee (1999), and Reid et al. (2008) reported that 13 of 30 HDD stream crossings had drilling mud releases (citing Harder Associates 1996). The statistic is based on drilling mud releases during the early days of HDD technology (first conducted in 1971). The summary by Reid and Anderson (1998) provides a substantive description of effects to streams and habitat in the cases with inadvertent returns.

Drilling mud releases during HDD construction can result from:

1. Circulation losses through highly permeable gravels;
2. Mud migration along rock joints or fractures which intersect with the river bottom;
3. Loss of pilot hole directional control resulting in the intersection with the river bottom or approach slope;
4. Drilling mud pressures exceeding ground stress, widening existing or creating new fractures (hydraulic fracturing), allowing for mud migration; or
5. Substantially different elevations of entry and exit drill locations. Resulting pressure head differences can cause substantial upland leakages of drilling muds once the drill bit nears the ground surface or when it breaks the surface.

Drilling mud releases may surface through river and streambeds, wetland bottoms, or at upland locations. The volume of mud released to the surface would depend on:

1. Porosity of the substrate transporting the mud;
2. Extent and size of the porous material;
3. Pressure exerted on the mud by the hydraulic system;
4. Viscosity of the mud at the time of exposure; and
5. Whether mud circulation can be maintained.

Magnitude of effects by mud releases to fish, streams and habitat would depend on the following (page numbers referenced from Reid and Anderson, 1998):

1. Toxicity of the drilling mud components and additives (pages 57-59; also Table 1);
2. Increased sediment loads (page 59);
3. Effects to hydrological conditions that would cause poor conditions for wetland plant establishment and growth (pages 59-60);
4. Release into streams and rivers that could cause increases in the downstream drift of stream macroinvertebrates (page 60); and/or
5. Level of exposure to fish (e.g., concentration), duration of exposure, lifestage of fish present, timing of release, and ability of the watercourse to remove or incorporate the released muds without degrading existing habitats (page 61).

The report by Reid and Anderson (1998) summarizes the general effects, known or hypothesized, associated with drilling mud releases but does not provide specific effects associated with each of the 13 instances cited.

Likewise, Canadian Pipeline Water Crossing Committee (1999) reported that drill mud seepage occurred in 36 of 146 cases of HDD cases reviewed with most significant leakage occurring at the drill entry or exit points due to different pressure heads with large differences in elevation between the two points. Leakage also occurred during reaming or pull-back. However, the report did not describe the effects to fish, streams and habitat in the cases with leakages or inadvertent returns. Potential inadvertent returns are more common near the HDD drill entry and exit locations; however, impacts to waterbodies are minimized by locating the drill entry and exit points away from the waterbody. The probability of an inadvertent return may increase when the drill bit is working nearest the surface (see GeoEngineers 2017a and 2017b) but is dependent on numerous factors including substrate characteristics, head pressure of the drilling mud, topography, elevation, and subsurface hydrology.

Benthic organisms, on which green sturgeon would feed, could also be affected by burial. However, bentonite is more likely to stay in suspension than settle when compared to common bottom sediment; therefore, in flowing water areas, effects to benthic organisms from burial from inadvertent return are likely to be low.

Hydraulic fracture typically occurs when the drill path passes through relatively weak cohesive soils with low shear strength or very loose granular soils. Loose and silty sands and soft to medium stiff silts and clays typically have a higher hydraulic fracture potential. Medium dense to dense sands and gravels and very stiff to hard silts and clays have a low to moderate hydraulic fracture potential. Unfractured rock, because of its high shear strength, typically has a low potential for hydraulic fracture. HDD installations with greater depth or in formations with higher shear strength may reduce the potential for hydraulic fracturing (see appendix E).

In the event an inadvertent return occurs into a waterbody, drilling fluid would enter the waterway causing short-term, temporary water quality impacts downstream of the project area including sedimentation and turbidity. The behavioral avoidance response of green sturgeon is presumed to be triggered within the immediate vicinity of the release, and the fish are expected to return and utilize the affected area shortly after the inadvertent release has been halted. PCGP's *Drilling Fluid Contingency Plan for Horizontal Directional Drilling Operations* (see appendix D) describes how the drilling operations would be conducted and monitored to minimize the potential for inadvertent drilling mud releases. The HDD Contingency Plan also includes procedures for cleanup of drilling mud releases. If significant concentrations are found during monitoring as a result of a release, the following possible corrective measures would be taken:

1. Deployment of containment structures, if feasible, and removal of drilling mud from substrate and streambanks if possible.
2. Increase the drilling fluid viscosity in an attempt at sealing the point at which fluid is leaving the drilled hole. The drilling operation may be suspended for a short period (i.e., overnight) to allow the fractured zone to become sealed with the higher viscosity drilling fluid.
3. If increasing the drilling fluid viscosity is ineffective, lost circulation materials (LCM) may be introduced into the hole by incorporating them in the drilling fluid and pumping the material down-hole. The drilling operation may again be suspended for a short period (i.e., overnight) to allow the fractured zone to become sealed with the LCMs.
4. Depending on the location of the fractured zone, a steel casing may be installed that is of sufficient size to receive the largest expected down-hole tools for the crossing. This casing installation provides a temporary conduit for drilling fluids to flow while opening the remaining section of the hole to a diameter acceptable for receiving the proposed pipe sections. To alleviate future concerns with the steel casing after the HDD installation is completed, the casing is generally extracted from the hole prior to or just after completing

the HDD installation. However, there have been instances when attempts at extracting the steel casing were unsuccessful.

5. In the event drilling fluid flow is not regained through the annulus of the drilled hole and a steel casing installation is not utilized, the HDD contractor may elect to install a grout mixture into the drilled hole in an attempt to seal the fractured zone. The down-hole drilling assembly is generally extracted and existing hole is re-drilled to the point at which it had previously been drilled prior to having encountered the loss of drilling fluid.

In some instances, it may be determined that the existing hole encountered a zone of unsatisfactory soil material and the hole may have to be abandoned. If the hole is abandoned, it would be filled with cuttings and drilling fluid.

Overall at the site of any inadvertent return, the amount of drilling mud released into a waterbody would be low. The HDD location on the Coos Estuary and Coos River has a large volume of water and swift flows, where the drilling mud would be diluted. If an inadvertent release of drilling mud from an HDD occurred on the Coos River, it would have minor short-term adverse effects to aquatic resources including green sturgeon. Likewise, inadvertent release of drilling mud from one or both HDDs beneath Coos Bay would be expected to have minor short-term consequences to water quality and substrate composition and characteristics in the estuary.

Dispersion of drilling fluids from a release site (inadvertent return) is a function of the energy, salinity, and sediment transportation characeristics of the watercourse and the amount of fluid released. In low-flow areas such as tidal mudflats, releases will exhibit limited horizontal transport. If drilling fluid is released into Coos Bay, the drilling fluid will not likely mobilize as it would in a rapidly moving river (Reid and Anderson 1998). Coos Bay is relatively shallow throughout much of the HDD alignment. The mudline becomes exposed during low tides across much of the alignment except within the dredged shipping channel. In the event of a drilling fluid release into Coos Bay, the drilling fluid would likely settle onto the bay floor, where it could be contained and removed Pacific Connector Gas Pipeline 2017). Since marine bioassays suggest bentonite to be non-toxic (Reid and Anderson 1998), a coating of bentonite on mudflats would most likely create a temporary physical barrier to benthos burrows and interfere with species' feeding mechanisms, similar to existing depositional phenomena in the estuary. If drilling fluid is released into Coos Bay it would be addressed in accordance with the provisions of the containment plan (Pacific Connector Gas Pipeline 2017). It is unlikely that any drilling fluid released would remain on the bay floor and not be captured and cleaned up.

Turbidity Effects – LNG Vessels in the Waterway

Propeller wash from LNG vessels and tug boat propellers associated with the Project, as well as ship wakes (waves) breaking on shore, could cause increased erosion along the shoreline, re-suspend the eroded material within the water column, and displace bottom organisms due to bottom scour. This may affect the diversity and health of the benthic community regarding food availability and feeding conditions for foraging and migrating fish species. At high concentrations, suspended sediments can affect oxygen exchange over the gills, resulting in weakened individuals or mortality. Waves from vessels breaking on the shoreline can also cause fish stranding. The possible magnitude and effects of the proposed Project including approximately 120 inbound and 120 outbound LNG carrier trips per year on shoreline erosion were approximated by JCEP through model studies, the results of which are discussed below.

Overall effects on bank and bottom erosion and elevated suspended sediment effects are expected to be unsubstantial.

Model Parameters

To estimate the effects of waves and propeller wash from LNG vessels in Coos Bay, JCEP developed two separate model approaches. One was developed by Moffatt & Nichol (2008b) and another by CHE (2011). Both used similar baseline information but different approaches to determine likely effects on shoreline erosion. These models assumed that upon entering Coos Bay, LNG vessels would travel at approximately 8 to 10 knots (9.2 to 11.5 mph) within the first mile of the Coos Bay entrance. For the remainder of the route to the LNG Terminal, LNG vessel speed would be approximately 6 knots (6.9 mph) or less. Vessels would be assisted by tugboats during transit and docking. Both models assumed that the maximum speed of the LNG vessels would be 6 knots (6.9 mph) and made comparisons to natural waves' effects in the bay. The Moffatt & Nichol model (2008b) assumed about 200 vessel transits per year (combined inbound and outbound; about 180 combined vessel transits are proposed) of a 934-foot-long vessel traveling at about 6 knots (6.9 mph), which is the upper range of speed that may occur during transport within the Federal Navigation Channel for LNG vessels.

The CHE (2011) model, however, used the wake generated by the tugboat providing transport in the bay as it would be traveling at the same speed as the LNG carrier and would actually generate larger waves. CHE (2011) also compared the energy, size and effects of waves produced by proposed LNG carriers to those generated by existing large vessel traffic in the Coos Bay route as well as natural wind waves. Both models considered the effect of waves at varied locations from near the mouth of Coos Bay to near the docking facility of the LNG carrier (7 to 9 locations along the proposed LNG route for the two models). In consultation with state agencies (ODEQ and ODFW), CHE selected model points that were considered "sensitive" areas. Their model assumed 113 round trips (i.e., 226 vessel channel transits) of LNG carriers annually traveling at about 6 knots (6.9 mph) along most of the route but 4 knots (4.6 mph) near the airport.

A more recent vessel wake analysis was recently completed (Moffatt & Nichol 2017d). This study compared two modeling scenarios – "without project" and "with project." The "with project" scenario included the latest anticipated dredged depths for the Federal Navigation Channel, access channel, and marine slip. This study also incorporated the latest anticipated vessel characteristics for the new facility, which included 240 vessel transits, bulk carriers and tugs. For the "with project" scenario, all LNG carriers were assumed to travel no faster than 5 knots, with tugs traveling up to 10 knots outbound. Results of the 2017 wake analysis are summarized below.

Wave Model Results

The Moffatt & Nichol (2008b) model found that the maximum wave height generated would be about 1.1 feet. Although waves of this size occur throughout much of the bay, they only occur about 2 percent or less of the time annually based on the locations modeled. Among the seven locations chosen by Moffatt & Nichol, the model predicted that the waves generated would equal from 0.0 to 3.1 percent of the annual wave energy at these locations above the current wave energy level.

The CHE (2011) model compared the two measures of potential changes of shoreline waves from LNG vessel activity. The first was a comparison of single event (one vessel passage) shoreline wave energy (as measure by wave velocity) to that of existing large Coos Bay vessels that already occurs. The other comparison was overall cumulative yearly effect of LNG passage to that of existing vessels and that generated by natural wind waves. Their model results showed that the single passage events of LNG carriers would have slightly less shoreline wave impact (as measured by average wave velocity at the shore) per event than that of large existing vessel passage. Existing large vessel velocity was assumed to be 10 knots (11.5 mph), which is greater than the lower velocity of 6 knots (6.9 mph) typical of LNG vessels and likely affected this result. This model estimated example direct shore wave height to be less than about 0.6 foot for the assumed mean higher high water tidal conditions for LNG carrier passage.

The CHE model simulated varied natural wind and tidal conditions (1,080 total combination conditions) to estimate wave effects on the shore sediment transport. One example of data results for high wind conditions indicated a maximum wave height near 0.9 foot high at some shore locations (assuming a 22 knot [25.3 mph] west wind). The model results indicated that nearly all of the annual shoreline wave-generated sediment transport would be generated by natural wind waves (greater than about 90 percent at all locations modeled). Overall, the model estimated that additional waves generated by the new LNG carrier traffic could increase shoreline sediment transport at the modeled point by 5 to 8 percent over existing conditions (wind-generated waves plus existing large vessel–generated waves).

Overall, while both of the CHE models indicated some additional shore sediment movement could occur from the waves generated by the passage of LNG carriers through Coos Bay, the effects would be small because increased waves would occur infrequently, contribute a very small portion of total annual wave energy and sediment transport, and be within the normal magnitude of waves that naturally occur within the bay. Therefore, the total effect is likely to be within the range of natural annual variability of wave conditions.

Additionally, the analysis indicates that the outer mile of the entrance, where LNG carriers would be traveling at 8 to 10 knots (9.2 to 11.5 mph), may have higher vessel-generated waves because of the greater speed. However, this area is already less protected from naturally occurring ocean-generated waves (this region directly faces the ocean entrance) and likely has higher background naturally generated waves than the regions farther in the bay. Overall, increased sedimentation and disruption of aquatic nearshore habitat from additional tugboat and LNG carriers generated waves would be unlikely because of the factors noted above.

The results of the more recent vessel wake analysis indicates the drawdown generated by LNG carriers' departure and arrival under the proposed Project would be lower than existing conditions (0.4 - 0.5 feet for bulk carriers compared to 0.1-0.2 feet for LNG carriers at the shoreline). The predicted wave heights at the shoreline are higher with the tugs (0.6 – 0.8 feet) than with the bulk carriers under the proposed project. However, even the magnitude of tug wakes would be at the low end of the locally generated wind-wave heights ranging from about 0.5 to 3 feet (CHE 2011, Moffatt &Nichol 2017e). The wave effect on the shoreline from increased vessel transits can be managed by reducing vessel speed (Moffatt & Nichol 2017e).

Propeller Wash Model Results

Effects of propwash on bank and bed erosion were estimated by the CHE (2011) and Moffatt & Nichol (2008b) reports noted above. The two models estimated the likely bottom velocity and effects to sediment along the entire route. These models considered boat and bottom sediment characteristics in the area of interest and tidal levels when transport and docking would occur.

The Moffatt & Nichol (2008b) report indicated that along most of the route (approximately from CM 1 to the new access channel for the LNG Terminal) bottom disturbance would be slight within the Federal Navigation Channel. The bottom velocity caused by the propeller would be similar to the maximum velocity of peak tides (about 4 feet per second [ft/sec]). However, near the docking location, they estimated bottom velocity would be roughly double, or about 7 to 8 ft/sec. The report noted that along most of this route the main channel bottom is considered coarse (sand and sandstone). This type of substrate is hard to suspend and rapidly settles. Generally, along most of the route no marked bottom disturbance or sediment suspension would occur, as the increased velocity would be similar to maximum tidal currents. Within about the last half- to quarter-mile before reaching the slip (based on the point selected for modeling) is where bottom velocity is increased. Some increased bottom scour and locally elevated turbidity may occur in this area, but the effects would be limited in dimension. Disturbance would be limited, partly due to the coarse (mostly sand) bottom substrate that is relatively resistant to resuspension and rapidly settles.

The CHE (2011) report found slightly different results using a different model. It reported that maximum bottom velocity in a narrow band along the route would be 13 ft/sec, higher than the previous report. This report also noted that maximum velocity diminished rapidly from directly below the propeller to 0.6 ft/sec along the edge of the Federal Navigation Channel (150 feet from mid-channel), which is below levels that would suspend fine sediment. Based on model results, bottom velocity greater than about 4 ft/sec would occur only in an approximate 80-foot-wide band. Therefore, velocity generated by the propeller in excess of tidal flow velocity would be limited to a narrow band in the mid-channel, limiting the area where sediment may be suspended from propeller actions of the LNG carriers. Additionally, as noted by Moffatt & Nichol (2008b), this region is generally of coarser sediment that is less prone to suspension.

The CHE (2011) report also modeled likely bottom disturbance from existing large vessel transit (assumed 106 trips annually) in the bay and found that bottom velocity from these would be slightly greater than that of the LNG carriers (projected 113 trips annually). Therefore, during LNG transit, where these high bottom velocities occur, some sediment would be moved during arrival and departure. This would occur below the intertidal area. Turbidity would likely be slight due to the coarse characteristics of the Federal Navigation Channel sediment that is resistant to current induced suspension and have unsubstantial direct effect from elevated suspended sediment to green sturgeon.

The CHE (2011) report also modeled velocities and likely effects on sediment scour at the access channel and marine slip from the tugboat pushing of LNG carrier into the dock. Assuming very high power use by the tug to dock the LNG carrier, the model estimated maximum velocity on the far bank (about 275 feet from the propeller) would be mostly less than 2.0 ft/sec, which would be unlikely to erode the bank. Furthermore, this area would be armored so no erosion would occur. Near the bottom, maximum velocity in the docking channel would be about 2.16

ft/sec. Sediment analysis suggests that over 95 percent of the bottom material (mostly silt/clay size) in the access channel would be susceptible to suspension at this velocity. The report also estimated that bottom scour would be limited to about 2 inches over a limited bottom area (approximately 100 by 50 feet) in the access channel. Some bottom disturbance would likely occur during docking. In most cases, this disturbance is likely to be much less than estimated because of the conservative assumptions used for this model. Again elevated suspended sediment levels during LNG carrier docking are expected to be brief and have only short-term local effects to any green sturgeon in the docking area.

An updated 2017 prop wash memo (Moffatt and Nichol 2017e) included modeling the use of ship engines and tug assist for berthing and unberthing in the marine slip area. Results indicated high propeller wash velocities along the east side of the slip during unberthing. The largest bottom velocities (13.6 feet/sec) were estimated to occur on the eastern side of the Access Channel and the Slip near the MOF. During berthing, the largest bottom velocities (5.4 feet/sec) are expected to be near the western slope within the Slip and the Access Channel.

Scour depths were estimated to be nearly 0.5 feet due to propeller wash near the eastern side of the Access Channel and the Slip if there is no slope protection installed. However, slope protection is planned for each side of the slip, and for the east and west sides of the access channel. These results do not change the earlier conclusion that suspended sediment levels during carrier docking are expected to only have short-term localized effects to individual green sturgeon that may occur in the docking area.

Erosion and Runoff from the JCEP Upland Facilities

Impacts on marine resources could occur from the clearing of vegetation at the terminal, erosion and sediment runoff, and potential hazardous substance spills during construction. While no streams are present in the upland portion of the terminal, the removal of current vegetation could modify the character and amount of water runoff into the bay.

Nearshore vegetation clearing could indirectly affect aquatic resources in the bay. However, the amount of nearshore vegetation that would be removed for this Project is small. The existing disturbed shoreline near the South Dunes site would be used as a temporary laydown area.

During construction, uncontrolled increases in sediment runoff to Coos Bay could impact local aquatic resources. JCEP would prevent uncontrolled releases of sediment runoff during construction by implementing erosion control and revegetation measures from its Plan and Procedures. Additionally, accidental spills of hazardous materials (e.g., equipment fuel, oils, and paints) during construction could have effects on aquatic resources in the bay. JCEP prepared a draft site-specific SPCCP to minimize the potential for accidental releases of hazardous materials. BMPs for erosion and pollution control are outlined in appendix N – Conservation Measures.

Stormwater Discharge

Stormwater discharge has the potential to contain chemicals toxic to green sturgeon. However, the NPDES permit that the applicants would obtain requires discharges to not modify state water quality standards of the receiving water. The stormwater permit application states, "The permit registrant must not cause a violation of instream water quality standards." Since the water quality standards are designed to protect aquatic resources, including green sturgeon, the applicants are to ensure the standards are not exceeded, and therefore not cause adverse harm to the aquatic resources. Thus, issuance of the permit by the state should ensure that aquatic resources are protected. However, it is known that stormwater runoff often does result in chemical concentration values at the point of discharge in excess of EPA water quality criteria (WDOE 2009). The general characteristics of the stormwater system and levels of some discharge items are presented below.

The proposed stormwater management system is designed to direct any flow that does not come into contact with any equipment containing potential contaminants (grease or lubrication oil) to designated areas for treatment. . Treatment of runoff from areas that have low potential for oil or grease contamination will generally consist of on-site infiltration to treat for suspended solids. Cartridge filter vaults may also be used in some locations. Stormwater collected in areas that are potentially contaminated with oil or grease will be pumped or will flow to the oily water system. Primarily, these localized drains are located around equipment to contain grease and/or lubrication oil. The oily water from the collection sump overflows to the oily waste separator package which is equipped with plate type separation devices to remove any oil and grease washed down from the facility equipment. Recovered oil and grease is held in the sump and periodically pumped directly to storage drums for disposal. The oily water system will flow to the oily water separator package(s) before being treated and discharged to the IWWP. The facility will be designed to provide drainage of surface water to designated areas for disposal in accordance with 49 CFR § 193.2159. Stormwater collection and treatment facilities will be designed to meet regulatory requirements from the NMFS and ODEQ.

The proposed oil and grease treatment system is designed to limit discharges of oil and grease. This system design would ultimately need approval from the State to obtain the NPDES permit. The treatment system function is an additional level of protection for inadvertent spills that come into contact with stormwater. The facility is not designed to intentionally mix oil and grease with stormwater, and there are no continuous discharges of oil and grease from the LNG Terminal. Discharges from the LNG Terminal that could contain oil and grease would be directed to the oily water treatment system.

LNG Terminal Site

The LNG facility and marine LNG loading area will include various drainage elements to manage segregated networks for contaminated and uncontaminated water from designated areas. Liquid effluent from the LNG facility and marine LNG loading area consists mainly of water from rainfall, protection of equipment with fire water, processing areas, storage areas, domestic areas, and utilities units. Water from all oil-filled equipment in LNG spill impounding basins will be pumped by submersible pumps to the oily water treatment system. Stormwater from areas other than LNG spill impounding basins will be collected in a system of stormwater swales, a buried storm water system, infiltration basins, and other treatment facilities. Stormwater facility overflow outfalls will ultimately connect to Coos Bay.

The stormwater management plan has been prepared to address stormwater system design, which would require approval from ODEQ (see Storm Water Management Plan appended to JCEP's Resource Report 2). Impervious surfaces associated with the LNG Terminal site include concrete at operational laydown areas, vehicle offloading areas, secondary containment areas, and working areas for operational maintenance. General surfacing in other areas where operational maintenance access would potentially be required would be dense-graded aggregate. In the areas of the Administration building and the Southwest Oregon Regional Safety Center (SORSC) building, finished surfacing would be asphalt for the parking lots and concrete for the helipad. The gas metering station would be surfaced with dense-graded aggregate. Runoff would be separated into either the stormwater system or the oily waste system. Stormwater with a high potential to encounter oil and grease pollution would be contained via curbs or other means and routed to an oil/water separator prior to disposal through the Industrial Wastewater Pipeline (IWWP) according to the applicable the NPDES permit requirements. For areas of the site where stormwater has a low potential to encounter oil and grease pollution, the first flush of stormwater would be treated onsite by either infiltration facilities, flow-through type cartridge filter devices, or vegetated side slopes. Infiltration facilities would provide treatment for the majority of the stormwater falling on the site. The facilities would be designed to capture and infiltrate all stormwater for 100% of the 2-year, 24-hour storm. Overflows from the infiltration facilities would be routed to pipe outfalls in the slip and Coos Bay. For locations that are not feasible to infiltrate, stormwater would be routed to cartridge filter devices, where the treated effluent would be discharged to Coos Bay. Stormwater from access roads to the site would flow through vegetated side slopes or ditches for treatment prior to being discharged to natural grade.

Industrial wastewater would be conveyed to the Port’s existing ocean outfall, pursuant to the NPDES permit issued by the Oregon Department of Environmental Quality (ODEQ). Stormwater collection and treatment facilities would be designed in consultation with NMFS and the ODEQ.

During construction, spills or leaks of hazardous liquids such as fuel or oil associated with construction equipment have the potential to reach surface waters including Coos Bay. Potential effects from a fuel spill would likely be short-term but could be detrimental to aquatic species within localized spill areas within the estuarine analysis area. Petroleum-based contaminants such as fuel, oil, and some hydraulic fluids contain polycyclic aromatic hydrocarbons (PAHs) which can be acutely toxic to the aquatic environment for fishes, and can also cause lethal and chronic sublethal effects to aquatic organisms (Breteler et al. 1985). Potential impacts from these spills would be avoided or greatly reduced by regulating storage and refueling activities, and by requiring immediate cleanup should a spill or leak occur. In order to avoid the contamination of surface water, the preliminary SPCCP, prepared for the construction phase; describes the measures that would minimize the potential for accidental releases of hazardous materials and to establish protocols concerning minimization, containment, remediation and reporting of any releases that occur. The SPCCP would be included as part of the NPDES permit.

The operation of the LNG Terminal would not require or produce large quantities of hazardous materials. Solvents and paints would be used during normal maintenance activities and would be kept in specialized containers with secondary containment to prevent spills. Within the LNG Terminal would be a system of curbs, drains, and basins that contain and collect accidental spills or leaks, thus preventing releases into Coos Bay that may impact water quality and reduce feeding opportunities for aquatic species within the estuarine analysis area. For the operational phase of the LNG Terminal, the preliminary SPCCP, to be included as part of the NPDES permit, would minimize the potential for accidental releases of hazardous materials and to establish proper protocol concerning minimization, containment, remediation, and reporting of any releases that occur. This SPCCP would meet the requirements of 40 CFR Part 112.

If a spill were to occur, the hazardous material from the concrete basins would be collected and trucked offsite to appropriate disposal areas. In the unlikely event that an accidental spill of LNG were to occur, no effects on marine life are anticipated. LNG is not toxic and, if spilled on water, would vaporize when exposed to the warmer atmosphere, and this vapor, being lighter than air, would rise. LNG is not soluble, does not mix with water and would not result in effects to marine life.

During the operation of the LNG Terminal, LNG carriers calling on the LNG Terminal could have accidental releases of fuels or other contaminants found on all ships. Since there is no planned bunkering (loading of fuel oils) for the LNG carriers, these spills would be limited to small inadvertent spills of petroleum-based fuels and lubricants from equipment onboard that would be managed according to the carrier's oil spill response plan. These products are kept in relatively small quantities on ships and therefore would not result in the types of volumes associated with a spill from an oil tanker. Depending on the timing, weather conditions, and the efficiency of the response and cleanup, localized adverse impacts may still occur depending on the proximity to aquatic habitat.

Trans Pacific Parkway/US-101 Intersection Widening

Stormwater generated as a result of new impervious area at the Trans Pacific Parkway/US-101 Intersection Widening would be collected and conveyed to treatment facilities to provide treatment for 100% of the 2-year storm event. Drainage curbs would be installed near the edge of pavement along the northwest side of the roadway. These drainage curbs would collect and convey flow from the road crown to water quality treatment facilities. The water quality facilities would provide treatment for the design flow volume and bypass higher flows before discharging the runoff into Coos Bay.

Kentuck Project Site

Roadway improvements associated with the Kentuck Project, which include elevating and re-paving East Bay Drive and Golf Course Lane, would result in the addition of new impervious area. The stormwater facilities at the Kentuck Project site would be designed to provide treatment for 100% of the 2-year storm event wherever feasible.

East Bay Drive would sheet flow stormwater runoff to roadside drainage curbs. Once along the curb, water would flow toward cartridge filters which would treat water before discharging the runoff onto rip-rap road base adjacent to the receiving waters in Kentuck Inlet.

Along most of Golf Course Lane, surface water ditches and flow-through bio-infiltration conveyance systems are proposed. In these areas, collected flow that does not fully infiltrate into the underlying well-draining soils would be conveyed to an outfall into the Kentuck Slough. At the north end of Golf Course Road, runoff would be collected in drainage curbs and conveyed to cartridge filters before discharging to Kentuck Slough.

Temporary Construction Facilities

Construction laydown areas would be surfaced to a large extent with larger, open-graded aggregate that would allow infiltration; therefore, stormwater from these areas would be self-contained and would infiltrate without the need for outfalls. Impervious surface would not be added at the Pony Village and Myrtlewood Offsite Park & Rides for the JCEP Project Area.

Stormwater treatment for temporary facilities is described further in JCEP's Resource Report 2 (Storm Water Management Plan appendix), and the ESCP in an appendix to JCEP's Resource Report 7.

APCO Sites

APCO Site 1 (East) would be surfaced with dense-graded gravel and existing drainage patterns would be preserved to the maximum extent practical. Stormwater would be treated primarily by vegetated swales and filter strips. Fill placed on APCO Site 2 (West) would be surfaced with native vegetation. Additional storm water controls would be added if necessary. The bridge connecting APCO Site 1 and 2 is in preliminary design. The stormwater run-off from the bridge would be treated prior to discharge to Coos Bay.

PCGP Contractor Yards

PCGP has proposed contractor yards that border Coos Bay at the shore and another that borders Isthmus Slough at the shoreline, all designated critical habitat for coho. Although the yards are previously disturbed industrial sites, stored materials and surface runoff could enter green sturgeon critical habitat. Any potential risks due to surface runoff will be mitigated through implementation of an approved stormwater management plan.

Stranding from Ship Wake

Fish stranding can occur when fish become caught in a vessel's wake and are deposited on shore by the wave generated by the vessel's passing. Stranding typically results in mortality unless another wave carries the fish back into the water. Pearson et al. (2006), in a study of fish stranding, noted that a series of interlinked factors act together to produce stranding during vessel traffic. These factors may include water surface elevations, with low tides more likely to result in strandings than high tide; beach slope, with strandings more likely on low gradients than high; wake characteristics influenced by vessel size, hull form, depth underwater (draft), and speed with faster speed producing large wakes; and biological factors, such as numbers of small fish present near the shoreline and whether or not fish are strong swimmers. All of these factors can vary simultaneously, making it difficult to predict the location and to what degree strandings may occur. A few areas may have the potential to strand fish in Coos Bay. One is the mud flats on the west side of the Federal Navigation Channel along the Coos Bay and Empire Range that have beach morphology that has been shown to have potential for stranding, especially at low tide. Size of juvenile green sturgeons that have been reported caught in the Coos Bay estuary in the 1950s through the 1990s have varied from 40 cm to over 100 cm (15.7 to >39.4 inches) fork length or total length (Farr and Kern 2005). Since the Coos Bay system is not a known spawning area, small juveniles would be absent; the sizes of green sturgeon expected in the estuary are thus considerably larger than sizes of juvenile Chinook salmon (less than 9 cm) stranded by ship wakes in the Columbia River (Pearson et al. 2006) and may not be susceptible to stranding by ship wake.

Ship wakes produced by deep-draft vessels traveling at speeds greater than the estimates for LNG carrier speeds along most of the route have been observed to cause occasional stranding of juvenile salmon with no observed strandings occurring from vessels traveling under 9 knots (10.4 mph) (Pearson et al. 2006). The hull geometry of the LNG carriers is such that bow wakes are minimized, especially at the slower speeds of 4 to 6 knots that would occur during most of the transit route through Coos Bay. The one exception is near the Coos Bay entrance (first mile), when vessels may be traveling 8 to 10 knots in this portion of the waterway. While waves generated in this region may be larger than those generated farther in the bay, this is an area likely already receiving larger ocean-generated waves, so the vessel-generated waves would be little different than current conditions in this region. Therefore, the LNG carriers would be traveling along most of the route at speeds less than that observed (Pearson et al. 2006) to cause stranding. In models and research conducted by JCEP, wave heights produced by LNG carriers traffic would not exceed that of normal conditions in Coos Bay and overall waves would contribute to a small portion of the total waves that occur in the bay. In addition, the LNG carriers would be arriving and leaving at high tide, which is a period when gently sloping beaches are mostly covered and less likely dewatered from waves. Considering that LNG marine traffic (about 120 round trips per year) would enter and leave at high slack tide, have mostly low vessel speeds, and wave height would be in normal range, and that green sturgeon would be of larger size than those found to be stranded, it appears unlikely that the Project would substantially contribute to stranding of green sturgeon within Coos Bay.

Exotic, Invasive Species

Invasive species have the potential to modify the food base and induce other ecological modifications in the estuarine area of Coos Bay. NAS are aquatic species that degrade aquatic ecosystem function and benefits, in some cases completely altering aquatic systems by displacing native species, degrading water quality, altering trophic dynamics, and restricting beneficial uses (Hanson and Sytsma 2001). Within the Coos Bay estuary, over 67 NAS have been identified (ANSTF 2006).

NMFS (2005b) identified effects by exotic species as a risk to green sturgeons in the Southern DPS. For example, exotic species are concerns because of replacement of food items; the exotic clam *Potamocorbula amurensis*, was introduced to the Sacramento-San Joaquin River and Delta systems (California) in ship ballast water from Asia in 1988 and has become the most common food of white sturgeon. The clam was also found in the only green sturgeon so far examined and is known to bioaccumulate selenium (Linville et al. 2002), a toxic metal potentially causing teratogenesis or abnormal embryonic developmental (Lemly 1996). Further, rapid expansion of the exotic clam caused changes in the primary productivity and benthic community dynamics of portions of San Francisco Bay (Werner and Hollibaugh 1993; Nichols et al. 1990).

Loaded with water from the surrounding ports and coastal waters throughout the world, ships can carry a diverse assemblage of marine organisms in ballast water that may be foreign and exotic to the ship's port of destination. If water were transported from port to port, which is not what is proposed, this transfer of water could result in aquatic biological invasions. Invasive species threaten to outcompete and exclude native species and the overall health of an ecosystem, causing algal blooms and hypoxic conditions and affecting all trophic levels resulting in a decline in biodiversity. EPA developed specific requirements for ballast water treatment under the Vessel General Permit requirement under the CWA NPDES program to reduce the chance of releasing invasive organisms in U.S. waters in 2013 (78[7] Federal Register 121938 [April 12, 2013]). This regulation requires that beginning December 19, 2013, all newly built large vessels would be required to treat ballast water to kill potential invasive organisms, with older vessels of the size that would be used for the Project having some delay in implementation of this requirement (first scheduled dry dock date after January 1, 2016). The current ballast water exchange (BWE) process is mandatory under the National Ballast Water Management Program. Prior to implementing treatment of ballast water, all large vessels that would discharge ballast water within 200 miles of the U.S. coast would be required to exchange ballast water outside of this 200-mile area. This was originally established by Nonindigenous Aquatic Nuisance Prevention and Control Act of 1990 and further amended by National Invasive Species Act of 1996 and National Aquatic Invasive Species Act of 2003, amended in 2005 and again in 2007 (NEMW 2007).

The required treatment of water would ultimately be an improvement over the requirement to just exchange ballast water to “flush” potential invasive organisms outside of the 200-mile territorial waters of the U.S., which was reported to reduce organisms by 88 to 99 percent (NRC 2011). The new requirement for treatment level is to reduce most organism types to less than 10 living organisms per cubic meter of ballast water. While this requirement may not eliminate all risk of invasive species entering waters, it is a substantial measure that would reduce the risk of project actions introducing invasive organisms into waters of the project area. Several other regulations apply to ballast water management and discharge that would be followed by all LNG carriers; these regulations would also aid in both ensuring reduction of discharge of potentially invasive species and, through vessel inspections, that procedures are followed as noted above.

All ships utilizing the Port of Coos Bay are subject to the 2012 USCG Final Rule on Ballast Water Discharges. Pursuant to this Final Rule, in order to discharge ballast water into the slip area while concurrently loading LNG cargo, all LNG carriers are required to carry out an exchange of ballast water in waters beyond the EEZ, from an area more than 200 nautical miles from any shore, and in waters more than 2,000 meters deep, or utilize one of several USCG-approved Ballast Water Management (BWM) methods. It is expected that LNG carriers calling at the LNG Terminal would be required to exchange ballast water at sea, more than 200 miles offshore; therefore, the discharge of ballast water would comply with the 2012 Ballast Water Discharge Standards and the potential impact for ballast water to introduce invasive species of interest in Coos Bay would be negligible.

ODEQ recently revised the Oregon ballast water regulations to make the Oregon regulations more stringent for vessels arriving from “low salinity ports” by requiring ballast exchange in addition to the current Federal ballast water treatment requirements. This applies to vessels that represents a ”high-risk” for the transport and release of aquatic invasive species arriving from “low salinity ports” (like those in Oregon). A “low salinity port” is defined as a port where ballast water salinity is less than or equal to 18 parts per thousand (or when the vessel operator is unable to verify ballast salinity). A “High Risk Voyage” is defined as voyages originating in the “low salinity ports” that represents a “high-risk” for the transport and release of aquatic invasive species arriving from such “low salinity ports.” The new rules retain ballast water exchange requirements, in addition to meeting federal ballast water treatment requirements, for what is termed as “high-risk voyages.,”. This is a measure to protect Oregon’s low-salinity ports during a period when the reliability of new “first generation” ballast water technologies are proven to be effective for low salinity ballast.

LNG carriers would discharge ballast concurrently with the LNG cargo loading at the LNG Terminal. JCEP expects its terminal to be visited by 120 LNG carriers per year. Each LNG carrier would discharge approximately 9.2 million gallons of ballast water during the loading cycle to compensate for 50 percent of the mass of LNG cargo loaded.[2] The LNG loading rate is designed to be 10,000 m^3/hr (with a peak capacity of 12,000 m^3/hr), or 4,600 metric tons per hour (5,520 metric tons per hour peak); consequently, the ballast water discharge rate would be approximately 20,250 gpm. Typical LNG carriers have three ballast water pumps, each capable of 3,000 m^3/hr (13,210 gpm) rated capacity. JCEP estimates it would take approximately 24 hours at the terminal to load a vessel with LNG cargo.

The ballast water discharged at the terminal would be that from 200 miles out in the open sea. Therefore, it is expected, based on the existing and future procedures to eliminate discharge of invasive species, that LNG carriers would not likely cause exotic nuisance species to be introduced into Coos Bay. The release of ballast water from LNG carriers at the LNG Terminal would not have adverse effects on green sturgeon.

Another potential source of invasive species, other than LNG carrier ballast water, is transfer between waterbodies by construction equipment used in water, or other water transfer actions. USGS (2017) identified two NAS that may occur within the Coos Bay estuary: New Zealand mud snails (*Potamopyrgus antipodarum)* and brackish water snail *(Assiminea parasitologica)*. PCGP would not obtain hydrostatic test water from either Coos Bay or the Coos River, to prevent the spread of NAS from the estuary to inland watersheds. PCGP currently has procedures in the *Hydrostatic Testing Plan* (see appendix U), which includes measures such as inspection and cleaning of all dredge and similar equipment prior to use intended to reduce or eliminate the chance of spreading invasive species.

<u>Entrainment from Dredging</u>

After a review of dredging studies done through 1998, Reine et al. (1998) concluded that “much of the available evidence suggests that entrainment is not a significant problem for many species of fish and shellfish in many bodies of water that require periodic dredging.” Since the Coos River is not a known spawning area for this DPS of green sturgeon, smaller individuals that would be more susceptible to entrainment because of slower swimming ability, would not be present. In addition, green sturgeon have been found to often leave estuaries in the winter months, when dredging would occur. Considering these factors, their likelihood of being susceptible to entrainment during dredging, and their likely low abundance, it is not anticipated that construction dredging would impact green sturgeon.

<u>Entrainment and Impingement through Vessel Cooling Water Intake at the Terminal Dock</u>

During operation of the LNG Terminal, vessels at the export terminal slip may entrain marine organisms through cooling water intake needed for vessel power plant operations. The quantity of cooling water used depends primarily on size and type of vessel, time at the terminal, power source used while at the dock, and the amount of recirculation. LNG carriers would need to

[2] One cubic meter of LNG is 0.46 metric tons, which for the maximum size of LNG carrier authorized to call on the LNG Terminal (148,000 m^3) would be 68,080 metric tons of LNG per ship. Assuming 1 metric ton of seawater is 1.027 m^3, the amount of seawater ballast discharged (50 percent of the weight of the LNG loaded) would be approximately 34,959 m^3 (approximately 9.2 million gallons).

recirculate water while loading LNG at the berth. The amount of cooling water to be recirculated is a function of the ships' propulsion systems.

A steam propulsion LNG vessel's typical cooling water flow rate while at the berth is expected to be approximately 11,000 cubic meters per hour (m^3/hr) (2.9 million gallons per hour or 48,430 gallons per minute [gpm]). For a 148,000 cubic meter (m^3) vessel, this flow rate would result in a total of approximately 69.7 million gallons of water being recirculated during the 24-hour loading cycle of LNG cargo. If a dual fuel diesel electric propulsion system (160,000 – 170,000 m^3 ship) were used, the typical cooling water flow rates are expected to be approximately 3,200 m^3/hr (845,376 gallons per hour or approximately 14,000 gpm). This would result in a total of approximately 22 million gallons of cooling water being recirculated to the slip over a 26-hour loading cycle of LNG cargo.

Initial estimates are that 40% of the LNG vessels loading at the terminal would be steam propulsion and 60% would be dual fuel diesel electric propulsion. Over time, the trend is anticipated to shift to a greater number of dual fuel diesel electric propulsion LNG vessels, thereby reducing the total cooling water intake per vessel call in the future. Once the LNG fleet has been identified, cooling water flow rates and the amount of water required can be further addressed. Generally, the total water intake would occur over a 24-hour period during each loading period, about 110 to 120 times per year.

Water to cool engines would be taken in through the sea chests located on the bottom of the vessel hull. An LNG carrier usually has sea chests on each side of the hull. The lower unit is just above the keel of the ship, approximately 15 to 20 feet above the channel bottom. The typical sea chest is approximately 3.5 to 4.2 square meters covered by a screen with 4.5 mm bars, spaced every 24 mm. Currently, no additional screening system other than that already employed on the LNG carriers is proposed for water intakes. Additional finer mesh screens are located internally on the vessels to prevent larger items from entering the system. These screens would not meet NMFS (1997c) screening criteria for juvenile salmonids.

As presented in detail below under Oregon Coast coho salmon (section 3.5.3.3), zooplankton entrainment loss would occur from water intake. Some organisms small enough to pass through the screens covering the vessel's sea chests would be drawn in with the cooling water and would be lost from the population in the slip area. The loss of planktonic species through entrainment is likely to be insignificant relative to current population in the bay as loss rate would be well below estimated natural mortality in the bay (Shanks et al. 2011, and analysis below).

Additionally, since green sturgeon primarily feed on benthic organisms, losses of plankton in the water column would have very limited influence on their available prey source in Coos Bay. Thus, mortality of some plankton from water intake through the vessel sea chests, while docked, would have no detectable adverse effect to green sturgeon.

The estimated velocity at the opening of the cooling water intake for a steam propulsion system ranges from 2.2 to 4.4 feet per second (ft/sec) (0.66 to 1.3 meters/second), depending on the intake rate of cooling water used. The estimated velocity at the opening of the cooling water intake for a dual propulsion system is approximately 1.3 ft/sec (0.39 meters/second), depending on the intake rate of cooling water used. NMFS recommends an approach velocity of 0.33 ft/sec for screening systems for salmonids of less than 60 mm, and 0.8 ft/sec for larger juvenile salmonids (NMFS 1997c). These guidelines also include other requirements such as sweeping velocity and type and size of openings that are not present on these screens. The result is likely to be that fish at least up to fry and possibly larger juvenile size fish near the intakes may be entrained or impinged during cooling water intake. The intake velocities for cooling water are low enough that it is not anticipated that any larger organisms (fish, marine mammals, or invertebrates) would be impinged on the intake screen. This includes likely exclusion of juvenile green sturgeon due to their larger size from being entrained or impinged. Green sturgeon also primarily remain near the sea bottom, which would be away from the vessel water intake. Therefore, it is unlikely that entrainment or impingement during engine water intakes by a vessel at the terminal would occur or have adverse effects on green sturgeon.

Temperature Effects in the Marine Slip from Vessels at LNG Terminal

The LNG carriers would increase water temperature within the slip slightly while at the terminal through the discharge of water after its use for engine cooling. The engines would be running to provide power for standard hotelling activities as well as running the ballast water pumps. The activities that would require LNG carrier power and the assumptions used to develop the cooling water flow requirements are described in Moffat & Nichol (2017g). .

Analysis and numerical modeling were performed to identify potential impacts of LNG carrier cooling water discharge on water quality in the slip and adjacent area of Coos Bay. The modeling was initially performed with two different numerical models: the 3-D UM3 model and the DKHW model. The models simulate hydrodynamic mixing processes of submerged discharges and predict temperature fields and dispersion of non-conserved substances in ambient water bodies. Cooling water numerical modeling requires input of steady-state flow velocity in the modeling domain. The results of tidal flowing modeling using the SELFE model showed that ambient current velocities inside the LNG Terminal area vary, depending on tidal stage. Peak current speeds in the berth only exceed approximately 0.32 ft/sec less than two percent of the time. Therefore, for cooling water modeling, two steady state ambient flow velocities were assumed and used further in the analysis: high velocity = 0.32 ft/sec and typical velocity = 0.16 ft/sec.

Results of the modeling showed that for typical ambient flow conditions at a distance of 50 feet from the discharge point (LNG carrier sea chest), temperatures from dual fuel diesel electric LNG carriers would not exceed 0.3°C (0.54°F) above the ambient temperature. This difference would decrease with further distance. Based on estimated slip volume, this total heat could result in an average water increase for the total slip volume during one day when the carrier is loading from 0.03 to 0.06°F. No temperature effects would extend beyond the slip due to the much larger water volume of Coos Bay.

However, the slight increase in water temperature in the slip due to the release of engine cooling water while the vessel is at dock would be ameliorated by cooling of the slip water during cargo load, due to the fact that LNG is at a temperature of -260°F. There would be a heat exchange between the cold hull of the vessel and the surrounding slip water, as discussed below.

The results of the 2011 modeling described above were supplemented in 2017 with additional thermal plume modeling to investigate the extent of the regulatory mixing zone (RMZ) where cooling water discharge would be greater than 0.3 degrees Celsius above ambient (Moffatt & Nichol 2017g). The RMZ used in the temperature plume modeling is defined as the three-dimensional extent where water quality standards may be exceeded as long as acutely toxic conditions are prevented and fish habitat and other uses are protected. This modeling analyzed LNG carriers with capacity of 148,000 m^3 and 170,000 m^3. It also modeled cooling water discharges of 10 degrees to nearly 21 degrees Celsius into various ambient temperatures ranging from 8 degrees to 18 degrees Celcius and under constant and stratified salinity conditions.

In summary, this latest modeling showed that the largest RMZ was associated with steam-driven carriers and extended up to 79.2 feet and 22.1 feet in longitudinal and transverse directions respectively, with a vertical rise of 12.1 feet under peak summer temperature conditions. Dual fuel diesel-electric driven carriers had a substantially smaller RMZ that extended up to 36.5 feet and less than 7 feet in longitudinal and transverse directions, respectively, with a vertical rise of up to 1.3 feet. In the future, LNG vessels will trend more to dual fuel diesel electric propulsion systems thereby reducing the total cooling water intake per vessel call (Moffatt & Nichol 2017g). It is unlikely that the water temperature of the slip would be greatly increased from the release of engine cooling water, therefore, no significant adverse impacts on aquatic species in the bay are anticipated.

Fish and invertebrates are adapted to function over the normal range of conditions encountered in their environment. Moderate to large temperature increases have the potential to reduce fish and invertebrate growth and reproductive success, and, if high enough, cause direct mortality. Fish of the north Pacific, including those found in Coos Bay, are adapted to cool water conditions and could be adversely affected by sharp large increases in water temperature. Temperatures over about 24 to 26°C (75 to 79°F) would be considered lethal in the short-term (a few days) for salmonids (WDOE 2002). These temperatures would likely be similarly lethal to green sturgeon, which have demonstrated significantly reduced growth for larvae at 24°C (Cech et al. 2000). The temperature of the water in Coos Bay undergoes both seasonal and diurnal fluctuations. In December and March, the ocean and fresh water entering the estuary had similar temperatures, around 50°F. In summer, low stream flows results in a rise of temperatures in the bay, to above 60°F in September at CM 8 (Roye 1979).

It is expected that water temperature in the terminal slip influenced by engine water releases from an LNG carrier at dock is not likely to cause any direct adverse impacts on green sturgeon. First, engine cooling water released into the slip would only slightly increase water temperature for a limited distance away from the vessel. Second, the slight increase in water temperatures from engine cooling water releases would be offset by cooling from contact with the hull of a vessel loading LNG. Third, the volume of water in the slip, and exchanges during tidal cycles would further minimize temperature variations.

Effects of Operational Lighting

Localized changes in light regime have been shown to affect fish species behavior in a variety of ways (Valdimarsson et al. 1997; Tabor et al. 2004; Nightingale and Simenstad 2001). Disorientation may cause delays in migration, while avoidance responses may cause diversion of migratory routes into deeper, less protected waters. In some cases, increased light may attract both predators and potential prey species (Simenstad et al. 1999; Valdimarsson et al. 1997; Tabor et al. 2004). Green sturgeon are bottom oriented and would likely be less affected by shore lights than near surface and pelagic species like salmonids.

Nighttime construction is likely to occur in the estuarine analysis area for in-water work activities such as dredging or placing revetment, as well as on-water activities such as receiving deliveries at the TMBB or MOF. Construction lighting would be designed, installed, and operated at a level that allows construction work to be completed safely and effectively while minimizing glare to surrounding areas. Construction lighting would be directed only to the surface waters of Coos Bay when necessary, in order to minimize impacts to aquatic organisms. Lighting for in-water work would be limited to the area around each vessel and the area of the in-water work. For example, during dredging, the area under the crane boom for clamshell dredging or derrick arm for cutter suction dredging would be lit. Lighting is anticipated to be a mix of fluorescent and sodium fixtures around the vessels (dredge, barges, tugs, and support vessels) with larger sodium or halogen lights shining on the work area (i.e., the water) under the crane boom or derrick of the suction dredge. Lighting for on-water work, such as barge or ship unloading, would be limited to the vessels and adjacent landing areas. Final marine construction lighting requirements would be subject to review and approval by the USCG as part of the Construction Security Plan.

The lighting levels would be based on American Petroleum Institute standards. Lighting around equipment and facilities where routine maintenance activities could occur on a 24-hour basis would range from 1 to 20 foot-candles, and there would be 20 foot-candle lighting levels within the compressor enclosures. General process area lighting would be kept to a minimum, on the order of 2 foot-candles. As a point of reference, 20 foot-candles is close to the indoor lighting in a typical home, 2 foot-candles is typical of that found in a store parking lot, and 0.4 foot-candle is typical of residential street lighting. The lighting design would use high-pressure sodium light fixtures during construction and for the final plant.

Lighting at the LNG Terminal and onshore facilities would likely include a mixture of low-power fluorescent lighting and higher intensity security lighting that would primarily be located on shore, in and adjacent to the slip. No high intensity lighting would be present near the water except possibly during vessel docking. When an LNG carrier is not in the berth, the lighting would be reduced to that required for security. It would be focused upon the structures and not be in proximity to the water so as to serve as an attractant or deterrent to fish species. When an LNG carrier is at the berth, it would physically block the lighting on the berth from the slip waters and, due to its proximity to the slip wall, would block the fish from getting too close to the lighting on the berth. Lighting used at the LNG Terminal would be similar to that already in place at other Coos Bay facilities.

Lighting on the tug dock would be low intensity lighting for safety, providing sufficient light for personnel movements on the trestle out to the tug berth and for movement on the berth itself. There is no intention to provide lighting near the water line or high intensity lighting that would be associated with activities other than the simple berthing of the tugs at this location. The reduced lighting levels near the water would reduce or eliminate any behavioral effects to fish in the Project vicinity. JCEP plans to develop the details of its final lighting plan in consultations with the FWS, NMFS, and ODFW to minimize potential impacts on aquatic resources. Increased lighting from facility operations is not expected to substantially affect the Southern DPS of green sturgeon.

Acoustic Effects from Construction and Operation

Underwater noise may affect green sturgeon. State agencies in Washington, Oregon, and California along with federal agencies have developed interim noise exposure threshold criteria for pile driving effects on fish (WSDOT 2011a; Fisheries Hydroacoustic Working Group 2008; Popper et al. 2006). Interim noise exposure threshold criteria for pile driving effects on fish include: 1) a SEL_{cum} of 187 dB re 1 μPa^2 s for fishes more than two grams, 2) a SEL_{cum} of 183 dB re 1 μPa^2 s for fishes less than two grams, and 3) an SPL_{peak} of 206 dB re 1 μPa for all sizes of fishes (WSDOT 2011a). SEL_{cum} is the cumulative sound pressure squared, integrated over time, and normalized to one second. SEL_{cum} is calculated as SEL (single strike at 10 meters from the pile) + 10 Log (number of strikes).

Noise would be generated during excavation and dredging of the slip and access channel. Noise would also be generated when an impact hammer is used to install the piles to support the LNG berth and tugboat dock, the temporary mooring piles at the TMBB, temporary dredge transport pipelines at the ARCO Site, Kentuck Project and Eelgrass Mitigation site, temporary mooring piles for booster and off load barges used for Navigation Reliability Improvement dredging, APCO and Trans Pacific Parkway/US 101 Intersection Widening temporary work bridge piles, and the MOF fender piles. However, the sheet pile walls and LNG Terminal berth and tugboat dock piling installation would occur while the marine berth is still isolated from the bay by the berm.

Construction noise levels for the LNG Terminal are expected to be similar to typical commercial structure construction programs, which average from 47 to 57 dBA at 2,000 feet (H&K 1994). Noise levels 50 feet air distance from typical construction equipment (not including pile driving, or sheet wall installation) to be used at the site would typically range from about 70 to 90 dB (see table 3.3.2-1 under Western Snowy Plover). Typical noise generated from operations would be less. Considering that noise levels would be attenuated from this equipment into water, based on the interim NMFS criteria, levels of noise that could cause direct adverse effects to fish would be unlikely from typical equipment and future operations.

Some dredging activities may generate underwater noise levels that may be harmful to very small fish in close proximity to the activity. Fischer (2004) noted dredging source decibel levels of 172 and 185 at one meter (three feet) from the dredge. The upper range of these values exceeds the interim noise criteria for small fish (those less than two grams). Thus, small fish very near (within about a meter of) the dredging, may be harmed if they remained in the area for a period of time. Initial slip dredging would have some sediment removal from shallow water.. Small green sturgeon of the size to be affected by these noise levels would not be present in the bay because this system does not include a spawning population that would supply small sturgeon to this area. Since no very small green sturgeon would be present in the bay and the fact that harmful levels of noise would occur only at the site of dredging, it is expected that green sturgeon would not be in a zone considered directly hazardous from noise levels.

Potential underwater acoustic effects of in-water and land-based pile driving are addressed separately in the sections below.

Land-based Pile

Underwater noise may be generated by driving piles on land (dry piles) since some noise propagates through ground and sediments (especially through harder substrates such as rock and clay) and may transfer to the water column somewhere else (known as sound flanking).

Sound in the water column would be at a lower level than at the source (WSDOT 2011a) since most sound energy does not travel through water but through the sediment. The propagation of underwater construction noise from the "dry" impact pile driving associated with the MOF was modeled in several reports prepared by JASCO Applied Sciences (O'Neill and MacGillivray 2017; Wladichuk et al. 2017; Wladichuk et al. 2018). Wladichuk et al. (2018) modeled potential impacts of land-based pipe pile impact driving on fish using both current guidelines (FHWG 2008) and new proposed guidelines (Popper et al. 2014).

Previous noise studies investigated radii to marine mammal and fish threshold criteria from a pipe pile with the same diameter (36 inch (0.9 m)) but a shorter length (60 ft (18.3 m)), as well as different number of strikes in a 24-hr period and at 4 set-back locations behind the MOF (O'Neill and MacGillivray 2017, Wladichuk et al. 2017, Wladichuk and MacGillivray 2018). After receiving additional construction details, the most recent study examined the threshold radii from driving a 104.8 ft (31.9 m) pile at the MOF and at 98.4 ft (30 m) set-back distance behind the MOF using a reduced impact hammer energy of 65%. This study found that injury to fish from peak sound pressure levels (206 dB in current guidelines) would occur up to 37m from the face of the MOF. Also, this study predicted that injury to both small (less than 2 grams) and large (greater than or equal to 2 grams) fish from cumulative sound exposure levels (183 and 187 dB respectively under current guidelines) would occur up to 1,723 meters from the shoreline. This distance was the same for both 10,000 and 20,000 total impact strikes because in both cases this was the distance when the noise attenuated to the sound level considered effectively quiet (150 dB). Under proposed guidelines (Popper et al. 2014), modeled distances to injury were considerably less, although the distance to temporary threshold shift (TTS) was the same – 1,723 meters. Figure 3.5.1-2 shows the modeled extent of this potential zone of injury in the project area from land-based pipe pile driving at the MOF face for 206 dB peak and 187dB SEL. Based on the results of Wladichuk et al. 2018, installation of land-based piles at the MOF face would increase potential exposure of listed green sturgeon to underwater noise in an area encompassing the navigation channel from the MOF across the bay to the airport and southwest to the vicinity of Southport Lumber yard. These noise thresholds could be reached during pile driving of the 8 mooring bollards at the MOF that would take approximately 14 days to install. Individual fish occurring in this area during pile driving could experience physiological effects sufficient to cause injury.

Land-based pile driving at the MOF shown to generate injury-level in-water noise would be limited to the approved in-water work window, which is October 1 through February 15. This window would minimize potential interaction with green sturgeon, which are most likely to be in the bay during summer. Also, small green sturgeon that would be most susceptible to barotrauma from increased sound pressures would not occur in the bay due to the lack of a spawning population in the area.

In-water Pile

In addition to the large number of piles that would be driven on land, a smaller number of piles would be driven in the water column in various locations throughout the estuarine analysis area, mostly for temporary mooring of vessels and structures during construction. These piles are summarized in table 3.5.1-1.

TABLE 3.5.1-1

In-water Pile and Structures Summary

Project Component	Description	Pile Type	Installation Method	# of PIles	Pile Size (inches)
Temporary Material Barge Berth (TMBB)	Temporary – breasting/mooring	Steel Pipe	Vibratory/proof with impact	6	<24
Material Off-loading Facility (MOF)	Permanent – fender pile	Steel H-pile	Vibratory/proof with impact	12	18
Temporary Dredge Transfer Line	Temporary – mooring piles or spuds	Steel pipe	Vibratory only	TBD	<24
APCO Temporary Dredge Transfer Line Support Cradle	Temporary	Steel pipe	Vibratory only	5	24
APCO Temporary Work Bridge	Temporary – 3 piles per bent	Steel pipe	Vibratory/proof with impact	12	24
Dredge Off-loading Area at Kentuck	Temporary – piles or spuds	Steel pipe	Vibratory/proof with impact	16	24
Dredge Off-Loading Area at Eelgrass Mitigation Site	Temporary – piles or spuds	Steel pipe	Vibratory/proof with impact	16	24
Dredge Off-Loading at APCO	Temproary – piles or spuds	Steel pipe	Vibratory/proof with impact	16	24
Trans Pacific Parkway/US 101 Intersection Temporary Work Bridge	Temporary	Steel pile	Vibratory/proof with impact	36	24
Trans Pacific Parkway/US 101 Intersection	Temporary – sheet pile	Sheet pile	Vibratory only	TBD	TBD
Trans Pacific Parkway/US 101 Intersection	Permanent	Untreated timber pile	Vibratory/proof with impact	1,150	14
Total Steel Piles				Approx. 119	
Total Wood Piles				1,150	

Installation of both land-based and underwater piles would increase potential exposure of listed green sturgeon to underwater noise. If individual fish are close enough to a pile while it is being driven, injury or behavioral changes could occur. Most of the in-water piles would be driven with vibratory hammer only, which would essentially eliminate the potential for injury. However, if an impact hammer is required for proofing of the piles, for instance in the case of some of the longer term temporary piles (e.g., dredge booster barges), then fish would be exposed to disturbance and potential injury for some distance surrounding each pile driving location.

NMFS pile driving effects calculator was used to determine the threshold distances where injury and disturbance are likely to be encountered by fish of different sizes for vibratory and impact pile driving (see tables 3.5.1-2 and 3.5.1-3). Peak, SEL and RMS noise values were obtained from documented noise levels for vibratory and impact pile driving of 24-inch piles (the largest piles proposed for the project as described in Table 3.5.1-2). These noise levels have been summarized in WSDOT (2018) but have other sources such as Laughlin (2005) and CalTrans (2015). All values were measured at 10m. The rationale for using 3000 strikes was that all in-water piles will first be driven with vibratory pile driver, and an impact driver will only be used for proofing.

Based on these calculators, the following effect distances have been determined:

- For vibratory pile driving, fish would not experience injury from peak sound pressures. Physical injury from cumulative sound exposure levels would occur within 233 feet (71 meters) for larger fish (greater than or equal to two grams) and within 328 feet (100 meters) for smaller fish (less than two grams).

- For impact pile driving, fish would experience physical injury within 40 feet (12 meters) from peak sound pressures. Physical injury from cumulative sound exposure levels would occur within 1,712 feet (522 meters) for larger fish (greater than or equal to two grams) and within 2,415 feet (736 meters) for smaller fish (less than two grams). Disturbance could occur anywhere within 28,133 feet (8,577 meters) of impact pile driving. Disturbance is where individual fish could experience behavioral effects such as decreased foraging efficiency, changes in daily movements, movement of prey species, etc. due to impact pile driving.

It was assumed that temporary pilings could be driven anywhere along the navigation channel to support the NRI pump stations. The location and number of these pump stations is currently unknown, so it was conservatively assumed that they could be located anywhere along the navigation channel. Therefore, potential noise impacts from pile driving are shown along the entire channel. The extent of these distances would be limited in some cases by the physical interruption of land masses and sharp turns in the landscape. Figures 3.5.1-2 and 3.5.1-3 show the physical extent of underwater noise disturbance and injury thresholds measured above.

In-water pile driving would be limited to the approved in-water work window for the project, which is October 1 through February 15. This window would minimize potential interaction with green sturgeon, which are most likely to be in the bay during summer. Also, small green sturgeon that would be most susceptible to barotrauma from increased sound pressures would not occur in the bay due to the lack of a spawning population in the area.

Operation

The addition of approximately 120 LNG carriers to the existing average commercial traffic of 50 ships per year is predicted to increase the in-water sound level by 4.5 dB in the Federal Navigation Channel. The intensity of the sound pressure levels from vessel traffic can vary considerably. However, sound pressure levels are generally in the range of 112 to 160 dB, intensities that may influence organism behaviors or perceptions but are not great enough to cause physiological damage (Richardson 1995; Hastings and Popper 2005; Fisheries Hydroacoustic Working Group 2008).

It is expected that LNG carrier noise in Coos Bay would be less than in the marine analysis area as vessel speed and engine output would be greatly reduced, which affects the magnitude of sound levels. In the Hatch et al. (2008) study, an LNG carrier during travel produced sound levels (with 1 standard error) of 182 ± 2 dB re: 1 µPa at 1 meter that attenuated to 160 dB at 35 ± 11 meters and to 120 dB at 16,185 ± 5,359 meters (Hatch et al. 2008). Other than possibly within 1 meter of the vessel hull, these are all values less than the current interim noise levels for fish noted above.

Generally, response to noise impacts would be behavioral and perceptual, and not physiological in nature, as fish would tend to avoid the area during periods of high noise output. It is expected that operational noise would not have adverse effects on aquatic resources including green sturgeon.

Habitat Effects – Slip, Access Channel, Pile Dike Rock Apron and Navigation Reliability Improvement Sites

Construction of the LNG Terminal facilities would impact about 82 acres of existing estuarine habitat, of which 39.8 acres would be from construction of the slip and access channel and associated MOF (table 3.5.1-4). About 14.76 acres of intertidal to shallow subtidal habitat, including 1.9 acres of eelgrass habitat, and 0.06 acre of salt marsh would be modified to primarily deep subtidal habitat as a result of the dredging for the slip and access channel,. The dredging operation would change physical conditions of the bottom, locally altering the bathymetry and potentially altering the morphology and water currents. About 36.7 acres of upland habitat would be converted to open water, primarily deep subtidal habitat.

The construction of the proposed marine slip, pile dike rock apron, and access channel would impact local aquatic resources by removal or conversion of some habitats. The pile dike rock apron will convert approximately 2.3 acres of former estuarine habitat (eelgrass, intertidal, subtidal, etc.) into angular rock. This change in habitat will create a variety of effects to listed fish species, including providing new substrate for seaweeds that can provide cover, providing potential habitat for predators (particularly in subtidal areas), and interrupt normal shoreline drift processes by acting like a groin. Use of riprap in the proposed marine slip would have no significant impacts to listed fish. There would also be short-term turbidity from dredging in the bay, and additional erosion of the shoreline during construction activities could result in sedimentation. To control soil erosion and potential sedimentation, JCEP would follow the measures outlined in its ESCP.

There is also the potential for an accidental oil or fuel leak from dredging equipment to affect aquatic resources in the bay. To avoid or reduce impacts from oil or fuel leaks, JCEP developed Preliminary Draft SPCCPs for both construction and operation.

Prey species that are important for local fish species, likely including those for green sturgeon, rely on many of the same habitat conditions. Eelgrass habitat supplies a diverse habitat for fish (Murphy et al. 2000). Eelgrass is an important ecological component in Coos Bay affecting many species. For example, submerged aquatic grasses are important habitat for small prey species of adult lingcod (in Appendix B-2 of PFMC 2008). Submerged grass meadows provide cover and food for a large number of organisms including burrowing, bottom-dwelling invertebrates; diatoms and algae; herring that deposit eggs clusters on leaves; tiny crustaceans and fish that hide and feed among the blades; and, larger fish, crabs and wading birds that forage in the meadows at various tides. Eelgrass provides shelter for a variety of fish and may lower predation, allowing more opportunity for foraging. The protective structure attribute of eelgrass is primarily for smaller organisms and juvenile life history stages of fishes. Previous studies (Akins and Jefferson 1973) have reported that Coos Bay has 1,400 acres of lower intertidal and shallow subtidal flats covered by eelgrass meadows. Therefore, changes in eelgrass abundance may have food chain effects to green sturgeon.

Permanent eelgrass impacts at the access channel would affect less than 1% of the estimated total area where eelgrass was detected in lower Coos Bay. This impact would result in an unnoticeable and extremely localized, short-term loss in forage food available for green sturgeon. Located south of the impact site, the mitigation site would be created within an existing eelgrass bed to replace the narrow band of eelgrass habitat lost at the impact site. The mitigation site would take several years to develop, but it would result in a long-term benefit to eelgrass, listed fish, critical habitat, and EFH.

Benthic and epibenthic invertebrates that presently inhabit shallow intertidal and subtidal regions within the boundaries of the proposed access channel dredging area would be removed with the dredged material. Ghost shrimp and sand shrimp (adults, juveniles and larvae), amphipods, clams, Dungeness crab, and various fish species are important prey for green sturgeon.

Therefore, the loss of invertebrates and vertebrates at the access channel would result in a reduction in fish food available to green sturgeon in those areas affected by the Project.

Dredging at the four NRI sites will take place in deep subtidal habitat used by benthic organisms, macroinvertebrates, and demersal fishes (e.g., worms, clams, crustaceans, mollusks, flatfish, and Pacific sand lance) some of which serve as prey to green sturgeon. Entrainment from dredging could injure or kill these and other bottom-dwelling species that have limited mobility and move, rest, find shelter, and feed within the dredge prisms for these areas.

The NRI sites are located entirely within deep subtidal habitats along the FNC. Such habitat is less productive than shallow subtidal and intertidal habitats. Furthermore, the FNC is subject to periodic dredging and propeller scour which can disturb the associated benthic community. Benthic communities associated with mud substrates like those within Coos Bay, however, have been shown to recolonize to pre-dredging conditions within four weeks following dredging (Newell et al. 1998). Impacts to bottom-dwelling marine life where dredging is planned at the NRI sites, LNG terminal slip, and access channel, therefore, are expected to occur over a short-term duration. While it is anticipated that affected areas would recolonize by similar species within a month or two following dredging, the relative composition among species likely would be altered over the near term.

Direct mortality or injury from dredging is not expected for most pelagic fishes due to their swimming ability and behavioral tendency to avoid disturbance. Dredging could affect other bottom-dwelling fishes, however, such as Pacific sand lance (Ammodytes personatus) which frequently inhabit sands and fine-grain sediments for rest and predator avoidance. Sand lance are an important prey species for many marine mammals, birds (including marbled murrelet), and fishes (including Pacific salmon and green sturgeon). While sand lance could be subject to mortality or injury from proposed dredging, the timing and extent of their presence in the lower bay at the NRI sites has not been confirmed.

As noted above, the CHE (2011) modeling indicated during LNG transit, bottom disturbance from high bottom velocities would occur. This could result in some benthic organisms (potential green sturgeon prey) being disrupted and some sediment being moved during arrival and departure. Mobile organisms (e.g. crabs, shrimp) would be able to return to the region, while some benthic organisms may be permanently displaced. Turbidity would likely be slight due to the coarse characteristics of the Federal Navigation Channel sediment that is resistant to current induced suspension. Overall, some loss of benthic organisms may occur from LNG carrier propeller wash during each transport trip near the slip approach, but the magnitude would be small and likely less than currently occurs under each existing large vessel trip.

Benthic communities in Coos Bay inhabiting mud substrates recovered to pre-dredging conditions in four weeks (McCauley et al. 1977). However, recovery in estuarine channel muds has been reported in a review paper of dredging to be typically six to eight months (Newell et al. 1998). In the lower Columbia River, McCabe et al. (1997, 1998) noted benthic organism recovery in three months. Because of the large quantity being dredged, including areas not in the channel with more varied substrate, it may take longer than four weeks to completely recover.

Shading Effects

Shading from over-water structures reduces the amount of light available to phytoplankton and aquatic macrophytes. However, the area where shading from LNG Terminal facilities would occur is intended for industrial uses and not the creation of new habitat. The general habitat within the excavated slip would not be conducive for many marine resources because of depth and steep armored banks, so relatively few resources would likely utilize this newly created area. The slip would be created from an area that is currently upland, and therefore no shading of currently unshaded water habitat, and no net loss in productivity due to shading, would occur. Project components that potentially could shade the new open water created by the construction of the slip include those listed below.

- The tug dock would be built over an open water portion of the newly developed slip and would be about470 feet long by 18 feet wide. In addition, there would be 360 feet of 8-foot-wide floats for mooring and accessing the security vessels.
- The tug dock would be connected from shore by a pile-founded trestle.

Most fish, have developed countershading as an adaptation to avoid predation (Moyle and Cech 2000) from above (dark dorsal surface blends with bottom substrate) and from below (light ventral surface blends with light from the surface). Fish within a shaded area would be more easily detected by a predator, especially from below because light colored ventral surfaces would stand out against a shaded water surface. Predation potential, based on some observed fish behavior, is a concern (Nightingale and Simenstad 2001). However, actual increased occurrence in predator numbers from even substantial overwater structures has rarely been documented. Additionally, a review of many marina and pier studies has not documented actual increased predation at these facilities (Nightingale and Simenstad 2001). For example, marine marina studies have found no documentation of increased concentrations of juvenile salmonid predators and some predators such as birds may be of lower abundance than under natural shoreline conditions (Cardwell et al. 1980, and Heiser and Finn 1970, as cited in NMFS 2005c). The extent to which any of these predators affect juvenile green sturgeon in shaded areas created by the proposed action is unknown; however, the probability of this occurring is low since it shades less than one percent of the slip surface area and the dock is located at the north side of the slip

Direct and Indirect Effects – Riverine Analysis Area

Two waterbodies, Coos River and Stock Slough, are within the green sturgeon riverine analysis area. Potential effects of the Pipeline crossing of the Coos River were addressed above in the estuarine analysis area section since the crossing location is within a tidally influenced river reach, and the Coos River would be crossed by HDD along with two crossings of Coos Bay.

The Pipeline would cross Stock Slough at MP 15.11 approximately 220 feet upstream from the head of tide endpoint and designated critical habitat for Southern DPS green sturgeon. At that location, Stock Slough is classified as a minor stream, <10 feet wide with intermittent flow. PCGP would use dry open-cut construction, either with a flume or using dam-and-pump. While these methods would have limited impacts on streams and aquatic species, they could result in some erosion and turbidity, as discussed below. At the point of crossing, green sturgeons would not require salvaging during dry open-cut construction because adults or subadults would not be expected upstream from the head of tide in intermittent streams.

Flume. The flume method typically is used to cross small to intermediate flowing waterbodies that are either fish-bearing or non-fish-bearing streams. The flume technique involves diversion of stream flow into a carefully positioned steel pipe of suitable diameter to convey the maximum flow of the stream across the work area, and ensures that stream flow rate is not interrupted.

Dam-and-Pump. With the dam-and-pump method, stream flow is diverted around the work area by pumping water through hoses over or around the construction work area. The goal of this technique is to create a relatively “dry” work area to avoid or minimize the transportation of heavy sediment loads and turbidity downstream of the crossing. This crossing method may be used on all waterbodies where stream flow can be diverted by pumping around the work area.

Turbidity and sedimentation impacts associated with dry open cut methods are generally minor and temporary, lasting typically for only a few hours, and are associated with 1) installation and removal of the upstream and downstream dams used to isolate the construction area; 2) water leaking through the upstream dam and collecting sediments as it flows across the work area and continues through the downstream dam; 3) movement of in-stream rocks and boulders to allow proper alignment and installation of the flume and dams; and 4) when streamflow is returned to the construction work area after the crossing is complete and the dams and flume are removed.

Estimates of suspended sediment concentrations are presented in detail in section 3.5.3 (SONCC coho) and section 3.5.4 (Oregon Coast coho) and are not repeated here. Stock Slough is wthin the Coos Bay Frontal-Pacific Ocean fifth field watershed. Characteristics of channel conditions for streams within the watershed were derived from the ODFW (n.d.) Aquatic Inventory Project; average conditions of bankfull widths, bankfull channel depths, channel gradients and percent sand, silt and organics in streambed substrates in the watershed are assumed to apply to Stock Slough for analysis purposes.

Using the available data, including stream flow estimates during instream crossing periods designated by ODFW (2008) which extends from July 1 to September 15 for Stock Slough (which could be dry at the time of construction), modeled dry open-cut construction could generate suspended sediment concentrations from 11.1 mg/L at 637 meters downstream to 0.26 mg/L at 1,323 meters downstream if a flumed crossing is used and concentrations of 11.1 mg/L at 51 meters to 0.26 mg/L at 1,247 meters downstream if dam-and-pump construction is used to cross Stock Slough. In general, the duration for exposure to those concentrations would be approximately 2 hours for crossing a stream less than 10 feet wide. Use of severity of ill effects (SEV) models developed by Newcombe and Jensen (1996) for adult estuarine nonsalmonids (Model 5 in Newcombe and Jensen), the maximum concentration of 11.1 mg/L lasting for 2 hours would produce a SEV score of 6, equating to moderate physiological stress but effects to green sturgeon in Stock Slough would be sublethal according to the model for adult estuarine nonsalmonids.

In their review of TSS effects and SEV scores in relation to estuarine fish and shellfish, Wilber and Clarke (2001) determined that the Newcombe and Jensen (1996) Model 5 for estuarine nonsalmonids yielded erroneous results, predicting lethal effects at very low concentrations of suspended sediment. Wilber and Clarke (2001) revised Model 5 so that SEV scores would be reduced by one. With this revision, the SEV score of 6, derived from a concentration of 11.1 mg/L lasting for 2 hours , above, would be corrected to SEV =5, equating to minor physiological stress (increase in rate of coughing, increased respiration rate). No records of sturgeons’

(Acipenseridae) response to dose and exposure to suspended sediments were used in the development of Newcombe and Jensen (1996) Model 5 or in the corrected model described by Wilber and Clarke (2001) so the adjusted SEV model may not be applicable. Nevertheless, sediment generated by dry open-cut construction across Stock Slough would not cause lethal effects to green sturgeons if present in designated critical habitat downstream.

Habitat Effects –Pipeline

The same approach utilizing suspended sediment concentration and exposure to evaluate levels of risk to fish (Newcombe and Jensen 1996) was applied to quantifying effects of sediment on fish habitat, termed harmful alteration, disturbance or destruction (HADD) of habitat by Anderson et al. (1996). HADD risk includes concentration and exposure to sediment along with sensitivity of the habitat affected. As described above, SEV of 7 would equate to moderate habitat degradation. Based on the modeling similar to that conducted for SONCC coho and Oregon Coast coho, there would be no risk of suspended sediment generated during Pipeline construction reaching concentrations that would cause moderate habitat degradation in Stock Slough and designated green sturgeon critical habitat 220 feet downstream from the Pipeline construction site.

Cumulative Effects

Additional projects within the action area (estuarine analysis area and the marine analysis area) are anticipated as human population growth continues in the region. Associated road and commercial development, as well as maintenance and upgrading of existing infrastructure within the estuary, are likely to occur in the foreseeable future. For example, the Port owns and operates the Charleston Marina, the Charleston Marina RV Park, and Charleston Shipyard. As a component of the Port's economic development, the focus of the Charleston Marina Master Plan is to develop commercial fishing and seafood processing, recreational fishing and boating, tourism, and growth in the retail and commercial sectors. Other, similar economic developments in the region could occur and, if they did, could contribute to the region's human population growth which could be detrimental to Southern DPS green sturgeon within and around the Coos Bay estuary.

A standard of "reasonably certain to occur" is clarified as "those actions that are likely to occur, bearing in mind the economic, administrative, or legal hurdles which remain to be cleared." NMFS provides that "speculative actions that are factored into the cumulative effects analysis add needless complexity into the consultation process" (51 Federal Register 19933). No specific state or private actions have been identified within the action area that meets this standard. Furthermore, activities described above are somewhat speculative in nature and cannot be quantified here. Therefore, a logical conclusion is that there would be no cumulative effects to green sturgeon associated with the proposed action.

Within the action area, gradual habitat and water quality improvements may also occur over time as federal, state and private conservation and habitat enhancement efforts are implemented. There are a number of potential federally permitted projects (e.g., repair of the entrance jetties and widening and deepening of the lower portion of the Federal Navigation Channel) that could result in cumulative effects. However, since these projects would require federal permits, their impacts would be evaluated through the federal permitting process when and if they occur.

The vessels transiting to and from the LNG Terminal would contribute to the ambient noise levels in the marine analysis area. However, the contribution of additional noise would occur within a context of diminishing traffic-related noise (Andrew et al, 2011), so the cumulative impact should be limited. In addition to the fishing fleet housed in Charleston Marina, current commercial traffic into Coos Bay includes about 60 deep-draft cargo ships and 50 barges. While this may remain constant for the near term, in the future non-fishing commercial traffic into Coos Bay may increase if the Port is able to make its planned improvements to attract new customers. However, even with the addition of 120 LNG carriers per year visiting the LNG Terminal, commercial ship traffic into Coos Bay would probably not reach historic levels. In the mid-1990s, as many as 200 non-fishing commercial ships per year called on the Port.

Even with the uncertainty generated by available data, there is a reasonably foreseeable increasing trend, albeit imprecise, for vessel traffic volume in the future although unforeseen global events such as future economic crises could influence the predictions. Although there would be a greater risk of noise to green sturgeon as a result increase ship traffic, because Project effects are expected to be minor, cumulative effects in the marine analysis area are expected to be insignificant.

Releases of diesel fuel and/or gasoline by commercial and recreational vessels are possible. According to annual reports published by the Pacific States/British Columbia Oil Spill Task Force (2002), ODEQ reported 34 spills from fishing vessels or other harbor craft in 2002, 38 spills in 2003, and 7 spills from fishing vessels plus spills from 27 other vessel types in 2004. Those relatively consistent incidences apparently increased in 2005 with 18 spills from fishing vessels 20 from recreational vessels, and 27 spills by other vessel types. By contrast in 2006, there were 3 spills from fishing vessels, 6 spills from recreational vessels, and only 6 spills from other vessel types. Though not known, it appears that the background rate of spills off the Oregon coast (incidence of spills in proportion to total vessel operation) by fishing vessels, recreation vessels, and other vessel types is generally low. Based on existing information, future rates of off-shore releases are also expected to be low and potential for green sturgeon to be affected by contamination by oil and other pollutants is not expected to increase above existing levels.

Considering the potential effects to green sturgeon in the marine and estuarine habitat described above, cumulative effects are likely to be minimal. This is based on the fact that non-federal actions like shipping traffic within Coos Bay, petroleum product spills at sea, and estuarine development and dredging, are unlikely to substantially increase in the foreseeable future.

Critical Habitat

Coos Bay has been included in estuarine critical habitat for the species. The Coos Bay estuary provides several PCEs including food resources, migratory corridors (passage) between estuarine and marine habitats, and sediment quality and water quality (NMFS 2009c), all of which are necessary to support various green sturgeon life stages. Similarly, coastal marine waters 110 meters (60 fathoms) deep or less, between Coos Bay and San Francisco Bay provide food, passage, and water quality as PCEs. Within Coos Bay, NMFS (2009c) noted that in-water construction or alterations, point and non-point source pollution, and LNG projects could affect the estuary portion of designated critical habitat. Project-related effects to Southern DPS green sturgeon within the Coos Bay estuary are likely to be similar to those discussed above including the following: 1) turbidity effects to forage/prey species and habitat by dredging, 2) shading effects on marine plants, 3) introduction of exotic species, 4) ship wake, and 5) pile driving.

Overall, adverse short-term effects would occur to the critical habitat of Southern DPS of green sturgeon from modification of nearshore and bottom habitat from slip construction, modification of bottom habitat from Navigation Reliability Improvements dredging which would disrupt food supply.

Similar to the modeling conducted for SONCC coho (section 3.5.3) and Oregon Coast coho (section 3.5.4), there would be no risk of suspended sediment generated during Pipeline construction reaching concentrations that would cause moderate habitat degradation in Stock Slough and designated green sturgeon critical habitat 220 feet downstream from the Pipeline construction site.

3.5.1.4 Conservation Measures

The proposed Project would implement a comprehensive suite of BMPs to avoid and minimize potential impacts to estuarine habitat that could be used on an intermittent basis by adult foraging green sturgeon. These BMPs are detailed in many different project documents, including the DMMP, the SWMP, the Corps of Engineers 404 permit application, etc., and summarized in appendix N to this document. Several specific conservation measures are called out below for additional discussion.

Effects within the estuarine analysis area would be offset by wetland restoration mitigation at a the Kentuck Project (see appendix O/Compensatory Wetland Mitigation Plan). The permanent loss of the 2.08 acres of eelgrass by construction and operation of the LNG Terminal would be mitigated at an off-site proposed eelgrass mitigation location south of the west end of the Southwest Oregon Regional Airport; at this site approximately 9.3 acres of new eelgrass habitat would be created.

The interim loss of unvegetated mud flat (intertidal and shallow subtidal habitats) would be restored at a 3:1 ratio. Restoration would occur at the Kentuck Slough golf course, east of North Bend, where a portion of the golf course would be converted to intertidal and mudflat habitat to offset the estuarine impacts. Conversion would require removing existing levees and removing tide gates, actions that would reestablish tidal connections between former intertidal habitat within the golf course and Kentuck Slough. JCEP also proposes wetland mitigation to offset the effects on freshwater wetlands associated with the development of the LNG Terminal site, South Dunes site, and utility corridor and access road between the LNG Terminal and South Dunes (see appendix O/Compensatory Wetland Mitigation Plan). Overall, approximately 90 acres of estuarine habitat would be recreated and/or enhanced at the Kentuck site.

Potential acoustic impacts to aquatic organisms identified in the analysis above are based on worst case use of impact pile driving without any sound attenuations measures. There are a number of measures (listed below) which could reduce the peak and cumulative sound pressures, which in turn could significantly reduce the range of sound waves that could injure or disturb listed fish species. Installation of piles during various phases of the Project would use the following measures to minimize risk of physical injury to fish:

- use vibratory pile driver whenever possible to minimize impulsive noise;

- use sound attenuation measures whenever driving in-water piles with an impact hammer;
- limit pile driving in the bay to the in water work window; and
- limit total impact hammer strikes on in-water piles per day to less than 3,000 or another amount determined in consultation with NMFS.

3.5.1.5 Determination of Effects

Species

The Project **may affect** green sturgeon (Southern DPS) because:

- adult and/or subadult green sturgeons may occur within the estuarine analysis area during construction and operation of the proposed action;
- adult and/or subadult green sturgeons may occur within the marine analysis area during operation of the proposed action; and
- green sturgeon may occur in Stock Slough which is included in the riverine analysis area during construction of the proposed action.

Some Project components are **likely to adversely affect** southern green sturgeon, including:

- short-term increase in noise generated from MOF land-based pile driving and in-water pile driving at various temporary construction sites throughout the bay may cause disturbance and physical injury to green sturgeon if individuals are in proximity to the noise during construction
- TSS could adversely affect green sturgeon. Exposure to TSS concentrations of 0.26 mg/l at 1,247 m downstream during dry open-cut construction (fluming or dam-and-pump) in Stock Slough for 2 hours could potentially equal SEV 5. Such an effect could cause minor physiological stress to green sturgeons if present in Stock Slough at the time of construction.
- on a localized basis, the proposed action may affect migratory and feeding behavior, potential food resources, and water quality (TSS) during the short-term construction period within the estuarine analysis area.
- localized bottom disturbance from project construction, which may reduce the abundance and diversity of benthic food sources in discrete areas of Coos Bay and cause direct impact to individual listed fish.

Critical Habitat

The Project **may affect** critical habitat for the green sturgeon (Southern DPS) because:

- the riverine analysis area includes Stock Slough which is included in designated critical habitat;
- the estuarine analysis area includes the Coos Bay estuary which is included in designated critical habitat; and
- the marine analysis area includes coastal marine waters up to 110 meters (60 fathoms) deep, which have been included as coastal marine critical habitat.

While several Project actions are not likely to cause adverse effects to critical habitat, some effects from Project components **are likely to adversely affect** critical habitat for southern green sturgeon because:

- bottom disturbance from construction would locally affect the abundance and diversity of food sources and habitat usability within discrete areas of Coos Bay;
- suspended sediment produced during dry open-cut crossing Stock Slough, 220 feet upstream from designated critical habitat in Stock Slough, could affect water quality (PCE 4) in freshwater riverine critical habitat.

3.5.2 Pacific Eulachon (Southern Distinct Population Segment)

3.5.2.1 Species Account and Critical Habitat

Status

NMFS was petitioned on July 16, 1999, to list and designate critical habitat under the ESA for Columbia River populations of Pacific eulachon (Columbia River smelt) in 1999. NMFS (1999a) found that although eulachon catches within the Columbia River basin had recently declined, substantial scientific information was lacking to support the petition (NMFS 1999a). In 2007, the Cowlitz Indian Tribe petitioned NMFS to list the eulachon population south of the U.S./Washington-Canada Border as threatened or endangered under the ESA (Cowlitz Indian Tribe 2007). NMFS found that the 2007 petition did provide sufficient information to warrant delineation of a DPS for the eulachon south of the U.S./Washington-Canada border and that this population had substantially declined in abundance (NMFS 2009e).

NMFS listed the eulachon (Columbia River smelt), Southern DPS, as threatened in 2010 (NMFS 2010c). The Southern DPS includes eulachon spawning in rivers from California into British Columbia (NMFS 2008c).

Threats

Five primary threats to the eulachon include 1) climate change impacts on ocean conditions, 2) climate change impacts on freshwater habitat, 3) eulachon by-catch in offshore shrimp fisheries, 4) dams and water diversions in the Klamath and Columbia Rivers, and 5) predation in the Fraser and British Columbia coastal rivers (NMFS 2008c).

The most serious threat recognized throughout the four subareas is climate change impacts on ocean conditions. This is closely followed by climate change impacts on freshwater habitat and eulachon by-catch in offshore shrimp fisheries. Additional threats cited include dams and water diversions in the Klamath and Columbia Rivers and predation in the Fraser and British Columbia coastal rivers (NMFS 2008c).

Species Recovery

NMFS published a recovery plan for the Southern DPS of eulachon in September of 2017 (NMFS 2017h). The recovery strategy includes research and monitoring actions that include but are not limited to the following: 1) estimating long-term spawner abundance, 2) survival of larval eulachon, 3) evaluating importance of the tidal freshwater, estuary, plume, and nearshore ocean environments to the viability and recovery of eulachon in the Klamath, Columbia, and Fraser Rivers, 4) determining the significance of plume and ocean conditions that affect eulachon survival, 5) developing a marine abundance survey for eulachon and correlation with riverine abundance estimates, 6) determining the significance of climate-related impacts on ocean conditions that affect eulachon survival, and 7) determining the significance of water quality degradation by potential contaminants on eulachon recovery potential. Priority management recovery actions identified in NMFS (2017h) include: 1) establish a eulachon technical recovery and implementation team to develop an overall framework for funding, prioritization, implementation, and reporting of recovery actions; 2) develop outreach and education strategies regarding the ecological, economic, and cultural values of eulachon; 3) continue to work with the ocean shrimp trawl fisheries and the states of California, Oregon, and Washington to implement actions (e.g., fleet-wide implementation of light emitting diode lights, rigid grate bycatch reduction devices, and additional gear-type or operational modifications, to further reduce bycatch of eulachon in the ocean shrimp trawl fisheries); 4) continue to work with the states to implement a limited-opportunity eulachon fishery to:

> (1) provide essential context for interpreting historical harvest data to better understand trends and variability in eulachon abundance;
> (2) fill critical information gaps such as the length and age structure of spawning eulachon, as well as the temporal and spatial distribution of the run;
> (3) support the cultural traditions of Northwest tribes who rely on eulachon as a seasonally important food source; and
> (4) provide a limited public and commercial opportunity for eulachon harvest to maintain a connection between people and the eulachon resource.

5) continue to work with federal and non-federal entities that maintain and operate dams and channel-spanning water control structures to develop and implement actions to reduce the ecological effects caused by water management operations on riverine and estuarine habitats to support the full-range of biological requirements for eulachon; 6) continue to work with the U.S. Army Corps of Engineers to develop and implement actions to reduce impacts from dredging (e.g., entrainment, on eulachon); 7) continue to work with the states of California, Oregon, and Washington to implement programs that improve water quality for temperature; and 8) continue to work with federal agencies and the states of California, Oregon, and Washington to implement programs (e.g., revetment breaching and removal, to reduce the impacts of shoreline construction on eulachon and their habitats)..

Life History, Habitat Requirements, and Distribution

Pacific eulachon are an anadromous smelt endemic to the northeastern Pacific Ocean. They range from northern California to southwest and south-central Alaska and into the southeastern Bering Sea (NMFS 2013f). Adult eulachon usually spend three to five years in saltwater before returning to fresh water to spawn from late winter though early summer (NMFS 2009e). Eulachon generally spawn at night in rivers that are glacier-fed and/or have peak spring freshets, and it has been suggested that imprinting is confined to an estuary not a specific individual spawning river (Hay and McCarter 2000). The typical spawning temperature is from 4° to 10°C in the Columbia River and tributaries and from 0° to 2°C in the Nass River (NMFS 2009e).

Spawning time is mostly likely dependent on geographic location, with those individuals in the southern part of the range spawning earlier than their northern counterparts. Eulachon spawn earlier in southern portions of their range than in rivers to the north. River-entry and spawning begins as early as December and January in the Columbia River system (NMFS 2008c). Reports have indicated spawning beginning in January in rivers of the Copper River Delta of Alaska and in May in North California. Within coastal British Columbia, the typical pattern is reversed, with spawning occurring as early as February in the Nass River and the latest spawning occurring in April and May in the Fraser River. Data also supports the evidence of waves or runs of eulachon spawning in some basins (Hay and McCarter 2000). Most eulachon adults die after spawning.

Eulachon sexes must synchronize their activities closely because eulachon sperm remain viable for only a short time, estimated to be minutes (Hay and McCarter 2000). Eggs are fertilized in the water column, sink, and adhere to the river bottom typically in areas of gravel and coarse sand. Eulachon eggs hatch in 20 to 40 days, with incubation time dependent on water temperature. Shortly after hatching, the larvae are carried downstream and dispersed by estuarine and ocean currents (NMFS 2009e). After leaving estuarine rearing areas, juvenile eulachon move from shallow near shore areas to deeper areas over the continental shelf. Larvae and young juveniles become widely distributed in coastal waters, with fish found mostly at depths up to 15 meters (50 feet) but sometimes as deep as 182 meters (600 feet) (Hay and McCarter 2000). Eulachon larvae and post-larvae eat phytoplankton, copepods and their eggs, mysids, barnacle larvae, worm larvae, and other eulachon larvae (NMFS 2009e). Adults and juveniles commonly forage at moderate depths (15 to 182 meters) in inshore waters, feeding on zooplankton, primarily eating crustaceans (Hay and McCarter 2000). With their high lipid content and massing in estuaries and rivers during spawning migrations, eulachon are an important part of the Pacific coastal food web. Eulachon are prey to numerous fish, avian species, marine mammals, and terrestrial mammals (NMFS 2009e). Historically, eulachon distribution corresponds closely with the EPA's Coastal Range Ecoregion which extends from the Olympic Peninsula through the Coast Range and down to the Klamath Mountains and the San Francisco Bay Area. Streams within this region exhibit two distinct annual flow patterns: 1) streams draining coastal watersheds commonly experience winter rain events with periods of high flow; and 2) streams draining more interior areas, such as the Columbia and Cowlitz Rivers, have a distinct spring freshet period coinciding with snow melt. Eulachon production is highest in these latter interior systems (NMFS 2009e).

Population Status

The Columbia River has historically shown the largest returns of spawning population throughout the eulachon's range. A review of records has shown that eulachon spawning runs from California to southeastern Alaska have declined in the past 20 years, with a significant trend observed since the mid-1990s (Hay and McCarter 2000). From 1938 to 1992, the median commercial catch of eulachon in the Columbia River was approximately 1.9 million pounds. From 1993 to 2006, the median catch had declined to approximately 43,000 pounds, representing a 97.7 percent reduction in catch from the prior period. Despite a short increasing trend noted for the Columbia River from 2001-2003, recent catches remain lower than the historical median (Cowlitz Indian Tribe 2007).

Similar trends were noted by the Cowlitz Indian Tribe for tributaries of the Columbia River in Oregon and Washington, as well as Fraser River; a rapid decline in the mid-1990s, increasing returns during 2001-2003, and a recent decline to low levels (NMFS 2008c). The 2007 petition noted that the eulachon is most likely extirpated or nearly so in the Klamath River, Mad River, Redwood Creek, and Sacramento River (Cowlitz Indian Tribe 2007; NMFS 2008c).

Analysis of eulachon bycatch in ocean shrimp fisheries between 2007 and 2012 observed a greater than 40 percent annual increase in eulachon density, which was attributed to increasing population size (Ward et al. 2015). This same study also observed that coastal areas just south of Coos Bay are consistent hotspots for eulachon bycatch. This trend is supported by recent observations of increased eulachon population abundance (James et al. 2014).

Critical Habitat

Critical habitat for Pacific eulachon was designated in 2011 (NMFS 2011f). Critical habitat for eulachon includes freshwater creeks and rivers and their associated estuaries comprising approximately 335 miles of habitat within in 16 specific estuarine and freshwater areas in California, Oregon, and Washington. Essential to the conservation of the species are physical and biological features of freshwater spawning and incubation sites include water flow, water quality, water temperatures, suitable substrate for spawning and incubation, and migratory access for adults and juveniles. The physical and biological features of freshwater migration corridors include water flow, water quality and water temperatures to support larval and adult mobility; abundant prey items to support larval feeding (NMFS 2011f).

Activities that may affect the physical and biological features essential to the Southern DPS of eulachon include: 1) dams and water diversions; 2) dredging and disposal of dredged material; 3) in-water construction or alterations; 4) pollution and runoff from point and non-point sources; 5) tidal, wind, or wave energy projects; 6) port and shipping terminals; and 7) habitat restoration projects (NMFS 2011f). These activities may have an effect on one or more of the essential physical and biological features by altering alteration of one or more of the following: 1) stream hydrology, 2) water level and flow, 3) water temperature, 4) dissolved oxygen, 5) erosion and sediment input/transport, 6) physical habitat structure, 7) vegetation, 8) soils, 9) nutrients and chemicals, 10) fish passage, and 11) estuarine/marine prey resources (NMFS 2011f).

3.5.2.2 Environmental Baseline

Analysis Area

Two analysis areas are applicable to effects determinations for eulachon in the Southern DPS – the estuarine analysis area and the marine analysis area. Effects in the estuarine analysis area are associated with 1) operational activities by LNG carriers entering and exiting Coos Bay, 2) in-water construction activities including dredging and pile installation, and 3) the crossing of Coos Bay by the Pipeline. Eulachon occur within marine waters off-shore and within the marine analysis area where they could be affected by 1) underwater noise from LNG carriers, and 2) oil and fuel spills.

Species Presence

Although Coos Bay is within the historic range of the eulachon, south of the Columbia River mouth, eulachon have been identified in very few coastal streams (Cowlitz Indian Tribe 2007). Adults are found rarely in Coos Bay (NMFS 1999a) and spawning runs have not been documented for the Coos River. The BRT review of status of eulachon also concluded that their presence in Coos Bay was “rare” (NMFS 2008c). Observations of adult eulachon have been reported from the Umpqua and Rogue Rivers, Oregon (Emmett et al. 1991). Pelagic Tucker trawl samples over a 17-month period found larvae and small juveniles of a close relative, surf smelt, but no eulachon in the vicinity of the proposed terminal in Coos Bay (Shanks et al. 2011). Storch et al. 2014 reported that opportunistic sampling for eggs and larvae of eulachon was conducted in January and February 2011 in the Coos River, but nothing was found.

Coos Bay is known to occasionally support adult populations of eulachon (NMFS 1999a). When present, eulachon may utilize both shallow and deep water habitats within the estuary. Eulachon were captured in beach seine hauls in the Coos River estuary, June through September (NMFS 2008c). Based on current information, this analysis assumes that while adult eulachon may be infrequently present in Coos Bay, larvae are not present based on the lack of documented spawning in Coos Bay tributaries.

Critical Habitat

Small numbers of eulachon have been observed in a few coastal rivers and creeks in Oregon, including historical accounts of their occurrence in the Siuslaw River, Coos Bay, and Rogue River (NMFS 2008c). Critical habitat has been designated within the Lower Umpqua River. Eulachon apparently spawn and migrate within the lower Umpqua River from the mouth upstream to below the confluence with Mill Creek (NMFS 2011f). No critical habitat has been designated within the Coos Bay estuary or marine analysis area.

3.5.2.3 Effects of the Proposed Action

Some of the Project effects to Pacific eulachon, Southern DPS would be similar to those described above in section 3.5.1.3 for North American green sturgeon.

Direct and Indirect Effects – Marine Analysis Area

Project-related effects to the Southern DPS of Pacific eulachon within the marine analysis area could result from LNG carrier generated acoustic effects and oil, fuel, and gas spills.

<u>Acoustic Effects</u>

LNG carriers transiting the marine analysis area would produce underwater noise that may affect eulachon under certain circumstances. LNG carriers built in 2003 with 138,028 m^3 capacity were reported by Hatch et al. (2008) to produce sound levels (with 1 standard error) of 182 ± 2 dB re: 1 µPa @ 1 meter.

The criteria for noise levels considered harmful to fish are presented above in the green sturgeon discussion, but generally values less than 183 dB are not considered harmful to fish. As a result, only fish within about one meter (three feet) of the carrier would be in danger of direct noise harm. Eulachon, which tend to reside at midwater depths, would be highly unlikely to be within three feet of these carriers, and thus adverse effects to eulachon from LNG carrier noise are not expected.

<u>Fuel or Oil Spills at Sea</u>

The LNG carriers use either a steam or dual fuel diesel electric propulsion system that is primarily fueled by natural boil-off gas. Fuel (e.g., diesel) used for back-up generation for LNG carrier propulsion and oil or hydraulic fluids used for mechanical equipment could possibly leak or be spilled during waterway transits. The low volume of petroleum oils and fuel on LNG carriers greatly reduces chance of impacts in the marine environment from petroleum spills. The Federal Water Pollution Control Act, as amended by the CWA (33 U.S.C. 1251–1387), prohibits the discharge of oil upon the navigable waters of the U.S., Contiguous Zones (nine miles seaward of the three-mile limit), and, where it can be determined that the natural resources of the U.S. are impacted, out to the EEZ (200 miles). Also, LNG carriers calling on the LNG Terminal would be required by the Coast Guard to have a carrier response plan in order to be adequately prepared for accidental spills. Therefore, neither fuel nor oil leaks from LNG carriers transiting in the waterway to and from the LNG Terminal are likely to have adverse effects on aquatic resources including eulachon.

Direct and Indirect Effects – Estuarine Analysis Area

Potential project-related effects to the Southern DPS of Pacific eulachon within the estuarine analysis area are associated with: 1) turbidity from dredging, 2) turbidity from LNG carrier propeller wash and ship wake, 3) inadvertent return turbidity during the two HDD installations across the Coos Bay estuary, 4) stranding adult eulachon by LNG carrier wakes, 5) introduction of exotic, invasive species from ballast water, 6) entrainment and impingement of adult eulachon in LNG carriers' intake port, 7) elevated water temperature in the Terminal slip from the release of engine cooling water during LNG carrier cargo loading, 8) operational lighting, 9) underwater noise generated during LNG Terminal construction, 10) habitat modification from slip, access channel, NRI areas, and pile dike rock apron construction, and 11) restoration activities at the Kentuck Mitigation Site. Details on these potential effects would be similar to those discussed for green sturgeon in section 3.5.1.3.

Timing to Life History Functions

In-water construction of the JCEP Project within the Coos Bay estuary is planned from October 1 through February 15 following ODFW's recommendation. The two HDD installations may occur between March and December. Because eulachon spawning has not been documented in freshwater tributaries to Coos Bay, the estuary most likely only provides infrequently occupied habitats for eulachon. Seasonal presence of eulachon in the estuary has not been definitively documented but fish have been reported captured in the estuary from June through September (NMFS 2008c). If those reports are indicative of the seasonal presence of eulachon in Coos Bay, the timing of in-water construction would avoid such presence. The timing of HDD installation, however, may coincide with eulachon presence.

Turbidity

Turbidity would be generated at the LNG Terminal slip and access channel, Navigation Reliability Improvement sites, and Eelgrass Mitigation site; while peforming capital; and from the propeller wash of LNG carriers, tugs, and escort boats in the waterway during operation of the terminal (see discussion of direct impacts to green sturgeon within the estuarine analysis area in section 3.5.1.3, above). As discussed for green sturgeon above, turbidity in Coos Bay during dredging would be temporary, and there would be only limited areas where suspended sediment concentrations would be above ambient levels. Turbidity in Coos Bay caused by the Project is not likely to have significant adverse effects on eulachon. While dredging has been shown to have damaging effects on out-migrating eulachon larvae (NMFS 2017h), larvae are not expected to be present in Coos Bay based on the absence of documented spawning in Coos Bay tributaries. Similarly, no eggs are anticipated to be present in tributaries that could be smothered, entrained or damaged by proposed dredging activities. Should adult eulachon be present coincidental with LNG carrier traffic in the waterway, they would be expected to avoid the LNG carriers. Given the deep and shallow water habitats available, there is a low likelihood that temporary elevated levels of turbidity would result in significant impacts on adult eulachon in Coos Bay. It is possible, however, that individual adult eulachon could become entrained by hydraulic suction or clamshell dredging if they are present during the winter and early spring, but this is unlikely given the rare occurrence of the species in Coos Bay.

Similarly, individual adult eulachon could experience negative physiological and behavorial impacts from incremental increases of propeller wash at the new access channel and marine slip. These areas are expected to experience up to 0.5 feet of bed scour from propeller wash (Moffatt & Nichol 2017e).

Dredging at the four NRI sites will take place in deep subtidal habitat used by benthic organisms, macroinvertebrates, and demersal fishes (e.g., worms, clams, crustaceans, mollusks, flatfish, and Pacific sand lance) some of which serve as prey to green sturgeon. Entrainment from dredging could injure or kill these and other bottom-dwelling species that have limited mobility and move, rest, find shelter, and feed within the dredge prisms for these areas.

The NRI sites are located entirely within deep subtidal habitats along the FNC. Such habitat is less productive than shallow subtidal and intertidal habitats. Furthermore, the FNC is subject to periodic dredging and propeller scour which can disturb the associated benthic community. Benthic communities associated with mud substrates like those within Coos Bay, however, have been shown to recolonize to pre-dredging conditions within four weeks following dredging (Newell et al. 1998). Impacts to bottom-dwelling marine life where dredging is planned at the NRI sites, LNG terminal slip, and access channel, therefore, are expected to occur over a short-term duration. While it is anticipated that affected areas would recolonize by similar species within a month or two following dredging, the relative composition among species likely would be altered over the near term.

Direct mortality or injury from dredging is not expected for most pelagic fishes due to their swimming ability and behavioral tendency to avoid disturbance. Dredging could affect other bottom-dwelling fishes, however, such as Pacific sand lance, which frequently inhabit sands and fine-grain sediments for rest and predator avoidance. Sand lance are an important prey species for many marine mammals, birds, and fishes including marbled murrelet and Pacific salmon. While sand lance could be subject to mortality or injury from proposed dredging, the timing and extent of their presence in the lower bay at the NRI sites has not been confirmed.

At the Eelgrass Mitigation site, a total of 40,000 cy of dredge material will be removed most likely with a small hydraulic dredge. Modeled turbidity values were determined to range from 270 to 290 NTUs. The potential turbidity plume extents, defined by the simulated 10 NTU above background contour, from the excavator dredge area would be generally limited to between 340 and 360 feet in all directions (Moffatt & Nichol 2017c). Since the site is a more confined and shallow area with somewhat limited circulation, the turbidity plume would be maintained within the local area of excavation. The duration of suspended sediment settling, therefore, is expected to be very short with turbidity dissipating to background levels within an hour after dredge operations cease, depending on the tidal cycle.

Dredging is not anticipated to suspend or activate contaminants in the substrate that could have negative physiological effects on eulachon. A comprehensive sediment sampling and analysis plan (SAP) was completed in October 2006 in order to evaluate the grain size distribution and total volatile solids composition of sediments in the proposed dredge prism for the terminal access channel (SHN 2007). The testing that was conducted to determine whether the sediments meet Dredge Material Evaluation Framework (DMEF) guidelines, relative to Lower Columbia River Management Area, for in-water disposal. Since results of the study revealed that all samples were primarily composed of medium to fine grain sand and had a very low percentage of total volatile solids, no further chemical testing was required, and the sediments were considered suitable for in-water disposal per DMEF guidelines. Furthermore, the results indicate the sediment character should not result in significant increases in bioavailability of contaminants to fish and fish food organisms within the analysis area. Based on the results of the sediment sampling, there is little to no risk of contamination as a result of dredging the access channel.

Sediment evaluations conducted by the USACE in 2004 for the Coos Bay channel maintenance and improvement dredging along the Federal Navigation Channel (FNC) revealed only low levels of sediment contaminants, all below their respective DMEF screening levels. In 2011 and 2016, JCEP conducted geotechnical investigations at the NRI sites to support the JCEP's DMMP. Analysis of the physical character of sediments at the NRI sites determined that sediment composition consisted of sand, silty sand, sandstone, and siltstone. This is similar to sediments collected from the adjacent FNC and from within the footprint of the proposed LNG Terminal access channel. These sediments were generally described as coarse-grained with high sand content, which the Portland Sediment Evaluation Team (PSET) previously determined suitable for unconfined aquatic disposal. Due to their proximity to previous sampling locations in the FNC and access channel, sediments to be dredged from the NRI sites will have a similar chemical character which will be confirmed in future consultations with the PSET. Therefore, dredge materials from the NRI sites will also have a low likelihood of potential contaminants and be suitable for unconfined aquatic disposal.

<u>Turbidity Effects – Pipeline Construction with HDD</u>

Coos Bay would be crossed by two HDDs, one from MP 0.28 to MP 1.00 (West HDD), the other from MP 1.46 to MP 3.02 (East HDD). The Coos River (a tributary to the estuary) would also be crossed using HDD at MP 11.13. The horizontal crossing length of the West HDD would span 5,192 feet, extending from the North Spit to the southeast, crossing the Coos Bay navigation channel and terminating at North Point in North Bend, Oregon. The HDD profile would pass approximately 158 feet below the railroad trestle bridge and approximately 138 feet below the deepest part of the navigation channel. The depth and the locations of the railroad trestle foundations are unknown at this time (GeoEngineers 2017a). The feasibility analysis for the West HDD anticipates a relatively low risk of hydraulic fracture and drilling fluid surface releases occurring along most of the HDD alignment during construction. However, there would be a high risk of hydraulic fracture and drilling fluid surface release within about 150 feet of either end of the HDD due to the anticipated loose sand and decreased depth of cover. Installation of an oversized casing may be needed at both ends of the HDD path to assist in efficiently transferring axial loads to the drill bit, and to mitigate against hydraulic fracture and drilling fluid surface releases within the loose sand anticipated in the upper 30 feet (GeoEngineers 2017a).

The horizontal crossing length of the East HDD would span 8,972 feet extending from North Point in North Bend, Oregon eastward across Coos Bay and ending at the mouth of Kentuck Slough. Surface conditions at North Point at the west end of the HDD consist of a relatively flat ground surface covered with fill stockpiles. The east end of the HDD would be located within a flat grass vegetated area in Kentuck Slough Valley. The proposed depth of the Pipeline would be 210 feet below ground surface. Because of the length of the HDD, there would be an increased risk of drilling fluid surface release during reaming operations. This risk can be reduced by reaming the hole from both ends of the crossing. In general, GeoEngineers (2017a) expects the risk of drill hole instability along the HDD drill paths to be relatively low. Minor hole instabilities may be encountered within the very loose to loose soils expected along the upper portions of the HDD profile at the east end near Kentuck Slough, but that condition would not jeopardize the successful installation of the product pipe.

For construction using HDD across the Coos River (see appendix E), the design length of the Coos River HDD crossing would be approximately 1,602 feet. The proposed entry point would be located approximately 500 feet from the north bank of the Coos River and the the exit point approximately 630 feet from the south bank. The entry and exit points would allow for adequate depth beneath the Coos River. The preliminary design provides a minimum of 50.3 feet of cover below the Coos River. GeoEngineers' evaluation determined that the construction of the Coos River HDD crossing is likely feasible. GeoEngineers opined that there would be a relatively high risk of hydraulic fracture and drilling fluid surface releases along the first 500 feet and last 300 feet of the HDD, respectively. However, the risk of drilling fluid surface release to the Coos River would be relatively low.

Drilling requires use of a drilling mud for lubrication of the bit and removal of cuttings. A biodegradable bentonite clay mixture makes up drilling mud and is considered "practically non-toxic" (Reid and Anderson 1998). Because the drilling mud is under pressure during drilling, if the bit encounters substrate fractures or channels, it is possible for bentonite to escape from the hole (termed an "inadvertent return"). Bentonite can escape to the surface through fractures in the drilled substrate. However, bentonite is more likely to stay in suspension than settle if compared to common bottom sediment; therefore, in flowing water areas, effects to benthic organisms from burial from inadvertent return are likely to be low. The locations where any inadvertent return may occur in the Coos River would be affected less because of the dilution factor of the large volume of water from any spill. PCGP's *Drilling Fluid Contingency Plan for Horizontal Directional Drilling Operations* (see appendix D) describes how the drilling operations would be conducted and monitored to minimize the potential for inadvertent drilling mud releases. The HDD Contingency Plan also includes procedures for cleanup of drilling mud releases. If significant concentrations are found during monitoring as a result of a release, possible corrective measures would be taken as described in section 3.5.1.3 for North American green sturgeon.

Other Effects within the Estuarine Analysis Area

Other impacts on eulachon within the estuarine analysis area are not expected to be adverse, similar to the discussions for green sturgeons. Stranding of adult eulachon by ship wake is possible but unlikely given the low vessel speed of 4 to 6 knots that would occur during most of the transit route through Coos Bay. The size of adult eulachon that may infrequently enter the estuary is 20 to 30 cm (Moyle 2002), considerably larger than juvenile Chinook salmon (less than 9 cm) that were subject to stranding by ship wakes in the Columbia River (Pearson et al. 2006). As a result, eulachon that may be present in the estuary should not be susceptible to ship wake stranding.

The release of ballast water by LNG carriers during loading at the LNG Terminal should not introduce exotic, invasive species into Coos Bay. Nor should adult eulachon be entrained or impinged during the intake of engine cooling water by LNG carriers while at dock. The larger size and swimming ability of adult eulachon (no larvae would be present) would allow them to avoid the engine cooling water intake. Entrainment of eulachon from dredging activities is also unlikely due to the relatively large size and swimming ability of adult life stage, their likely low abundance, and mostly pelagic distribution in the bay. The release of engine cooling water by LNG carriers at the LNG Terminal would not significantly elevate water temperature in the slip, nor would eulachon be affected by operational lighting at the LNG slip.

Habitat effects of the proposed project, including potential effects of installation of riprap (such as at pile dike rock apron), will be less significant for eulachon, given their rarity in the bay.

Finally, increased underwater noise from pile driving and other construction related activities would be similar for adult eulachon as it is for green sturgeon, as discussed above. In-water pile driving would be limited to the approved in-water work window for the Project, which is October 1 through February 15. This window would minimize potential interaction with eulachon which, if present, would most likely be in the bay during spring and summer.

As discussed in section 3.5.1.3, Green Sturgeon, underwater noise can be generated by driving piles on land (dry piles). The propagation of underwater construction noise from the "dry" impact pile driving associated with the MOF was modeled for fish in several reports prepared by JASCO Applied Sciences (Wladichuk and MacGillivray, 2018; Wladichuk et al. 2018). Wladichuk et al. (2018) modeled potential impacts of land-based pipe pile driving on fish using both current guidelines (FHWG 2008) and new proposed guidelines (Popper et al. 2014). Previous noise studies investigated radii to marine mammal and fish threshold criteria from a pipe pile with the same diameter (36 inch (0.9 m)) but a shorter length (60 ft (18.3 m)), as well as different number of strikes in a 24-hr period and at 4 set-back locations behind the MOF (O'Neill and MacGillivray 2017, Wladichuk et al. 2017, Wladichuk and MacGillivray 2018). After receiving additional construction details, the most recent study examined the threshold radii from driving a 104.8 ft (31.9 m) pile at the MOF and at 98.4 ft (30 m) set-back distance behind the MOF using a reduced impact hammer energy of 65%. This study found that injury to fish from peak sound pressure levels (206 dB in current guidelines) would occur up to 37m from the face of the MOF. Also, this study predicted that injury to both small (less than 2 grams) and large (greater than or equal to 2 grams) fish from cumulative sound exposure levels (183 and 187 dB respectively under current guidelines) would occur up to 1,723 meters from the shoreline. This distance was the same for both 10,000 and 20,000 total impact strikes because in both cases this was the distance when the noise attenuated to the sound level considered effective quiet (150 dB). Under proposed guidelines (Popper et al. 2014), modeled distances to injury were considerably less, although the distance to temporary threshold shift (TTS) was the same – 1,723 meters. Based on the results of Wladichuk et al. 2018, installation of land-based piles at the MOF face would increase potential exposure of individual eulachon to underwater noise in an area encompassing the navigation channel from the MOF across the bay to the airport and southwest to the vicinity of Southport Lumber yard (Figure 3.5.1-2). Individual fish occurring in this area during pile driving could experience physiological effects sufficient to cause injury or mortality. Conservation measures may include sound attenuation to minimize risk of disturbance that may occur in the Project vicinity during construction as well as limiting land-based pile driving close to the MOF face to the in-water work window, which would minimize the risk of exposure of adult and migrating eulachon to increased noise. Finally, the larval life stage of eulachon, which would be most susceptible to barotrauma from increased sound pressures, is not expected to occur in the bay due to the lack of documented spawning populations in Coos Bay tributaries.

Cumulative Effects

The carriers transiting to and from the LNG Terminal would contribute to the ambient noise levels in the marine analysis area. However, the incremental increase in noise would occur within a context of diminishing traffic-related noise (Andrew et al, 2011), so the cumulative impact should be limited. Current commercial traffic into Coos Bay includes about 60 deep-draft cargo ships and 50 barges. While this may remain constant for the near term, in the future non-fishing commercial traffic into Coos Bay may increase if the Port is able to make its planned improvements to attract new customers. However, even with the addition of 120 LNG carriers per year visiting the LNG Terminal, commercial ship traffic into Coos Bay would probably not reach historic levels. In the mid-1990s, as many as 200 non-fishing commercial ships per year called on the Port. Therefore, increased ship traffic into Coos Bay is not likely to have significant adverse cumulative impacts on Pacific eulachon.

There is a reasonably foreseeable increasing trend for carrier traffic volume in the future. Unforeseen global events such as potential future economic crises, however, could influence such predictions. Although there would be a greater risk of noise to Pacific eulachon as a result of increased ship traffic, because Project effects are expected to be minor, cumulative effects in the marine analysis area are expected to be insignificant. In addition to noise, if the current trend of increasing pink shrimp harvest off the coast of Washington and Oregon continues, there could be an associated increase with eulachon bycatch (Wargo et al. 2014). However, this trend would operate independent of the ship traffic associated with the LNG Terminal.

The possibility exists for accidental releases of diesel fuel and/or gasoline from non-project related vessels in the foreseeable future. According to annual reports published by the Pacific States/British Columbia Oil Spill Task Force, ODEQ reported 34 spills from fishing vessels or other harbor craft in 2002, 38 spills in 2003, and 7 spills from fishing vessels plus spills from 27 other vessel types in 2004. Those relatively consistent incidences apparently increased in 2005 with 18 spills from fishing vessels 20 from recreational vessels, and 27 spills by other vessel types. By contrast in 2006, there were 3 spills from fishing vessels, 6 spills from recreational vessels, and only 6 spills from other vessel types. Though not known, it appears that the background rate of spills off the Oregon coast (incidence of spills in proportion to total vessel operation) by fishing vessels, recreation vessels, and other vessel types is generally low and expected to continue at low frequencies in the foreseeable future.

Considering the potential effects to eulachon in the marine and estuarine habitat described above, cumulative effects are likely to be minimal. This is based on the fact that factors that are not under other federal authorization, like shipping traffic within Coos Bay, spills of petroleum products at sea, estuarine development and dredging, and harvest rate of eulachon, are unlikely to change substantially in the foreseeable future.

Critical Habitat

Critical habitat has been designated for this species but none occurs within either the marine analysis area or the estuarine analysis area. No critical habitat would be affected by the proposed action.

3.5.2.4 Conservation Measures

Measures developed for application within the estuarine analysis area to conserve green sturgeon would also benefit the eulachon Southern DPS if they are present within the estuarine analysis area during construction and operation of the Project.

3.5.2.5 Determination of Effects

Species

The Project **may affect** Pacific eulachon (Southern DPS) because:

- adult eulachon may be present within the estuarine analysis area during construction and operation of the Project; and
- eulachon may occur within the marine analysis area during operation of the proposed action.

Project components are **not likely to adversely affect** Pacific eulachon (Southern DPS), because:

- no spawning population has been documented upstream of the project in tributaries to Coos Bay;
- eulachon larvae are not likely to be present in the action area due to lack of a documented spawning population in Coos Bay tributaries;
- individual eulachon adults are considered rare in the action area, and would most likely be present from late spring to late summer (i.e., June to September), outside the proposed in-water work window of October to February. Therefore, adult eulachon would not be exposed to elevated episodes of turbidity, underwater noise, contaminants, or other adverse effects;
- the proposed action may affect the abundance and diversity of potential food resources and water quality during the short-term durations of construction within the estuarine analysis area. These effects are discountable and insignificant given the species current status within the analysis areas;
- increased underwater noise from construction may affect adult eulachon in the unlikely event they are present in the estuarine analysis area during the in-water work period. This effect is discountable and insignificant given the species current status within the analysis area; and
- the proposed action may affect water quality during the long-term operation period within the marine analysis area. This effect is discountable and insignificant given the species current status within the analysis area.

Critical Habitat

The Project would have **no effect** on critical habitat for the Pacific eulachon (Southern DPS) because no designated critical habitat is present within the estuarine analysis area.

3.5.3 Coho Salmon (Southern Oregon Northern California Coast ESU)

3.5.3.1 Species Account and Critical Habitat

Status

The Southern Oregon Northern California Coast (SONCC) ESU coho salmon was listed as a threatened species in 1997 (NMFS 1997b). At the time of listing, NMFS estimated that there were less than 10,000 naturally reproducing SONCC coho (NMFS 1997b). The SONCC coho ESU includes all coastal tributaries to the Pacific Ocean between Punta Gorda, California and Cape Blanco, Oregon. It includes all naturally spawning populations as well as three artificial propagation programs, of which one, the Cole Rivers Hatchery (ODFW stock #52) located on the Rogue River, is within the Pipeline project area.

Threats

At the time the SONCC coho salmon ESU was proposed for listing, various factors were included as threats to West Coast salmon populations in general but were not specific to the SONCC ESU. Logging, agricultural practices, urbanization, stream channelization, dams, wetland loss, water withdrawals with unscreened diversions for irrigation, and mining were listed as development actions that threatened the survival of this ESU and two others (NMFS 1995). The result of these development practices caused increased soil erosion and stream sedimentation, degradation of riparian zones, increased water temperatures, decreased recruitment of LWD in streams, decreased habitat complexity, and damage to riparian vegetation. Overharvest by commercial and recreational fisheries, disease, drought, warming ocean temperatures, and artificial propagation with associated impact of hatchery populations on wild stock have been contributory threats to all West Coast salmon (NMFS 1995).

Prior to listing the species, NMFS published a status review in 1995 that included the SONCC coho salmon ESU (Weitkamp et al. 1995). In that document, all coho salmon populations in the ESU were depressed. In the Rogue River, wild coho salmon were heavily affected by hatchery production with little natural production in the mainstem. The declining trend of coho salmon was indicative that natural populations in the Rogue River and others within the ESU were not self-sustaining (Weitkamp et al. 1995).

NMFS' most recent status review was published in 2016 (NMFS 2016). The updated status review indicates that there has been no improvement in the status of SONCC coho in the last five years, and the ESU is at a heightened risk of extinction since the former status review conducted in 2011 (NMFS 2016b). Coho salmon populations continue to be depressed within the ESU as a whole, and the Rogue River stock has demonstrated a declining trend, though insignificant, since the last formal status reviews when an average increase in numbers of spawners had been observed (Good et al. 2005; Ly and Ruddy 2011). While the Rogue River run includes hatchery fish releases from the Cole Rivers hatchery, these hatchery fish are of Rogue River stock origin and are considered by NMFS as part of this ESU. Consequently, there is reduced genetic risk to wild stocks in the Rogue River. Ocean harvest of the Rogue-Klamath stock by commercial and recreational fishers has been controlled since 1999 (not to exceed 13 percent), and river harvest within the ESU has not been allowed since 1994 (with tribal harvests excepted).

NMFS (2016b) concluded that data collected at Huntley Park provide the best estimates of coho spawner abundance in the Rogue Basin. Long-term (35 years) analysis indicates that SONCC coho have had a significant increasing trend, but from 2001 to 2014 (12 years), the population showed a non-significant declining trend (NMFS 2016b). The current risk of extinction of SONCC coho in the Upper Rogue River is “Moderate,” as opposed to “High” for other populations in the Interior Rogue Stratum (NMFS 2016b). Other populations in the SONCC ESU appear to be decreasing, with negative trends have been thought to also be related to low marine survival (NMFS 2016d). Multiple projects conducted in the Oregon portion of the ESU have improved riparian habitats, decommissioned roads, treated stream crossings, improved fish passage by dam removal, and installed fish screens on diversions (NMFS 2016b).

Insufficient in-stream flow, limiting adequate habitat for juveniles rearing during summer, has become a greater risk factor as groundwater and surface water withdrawal have increased due to crop irrigation and residential use. Water temperatures throughout the ESU have likely increased in summer during the ongoing drought; higher temperatures can limit migration, reduce growth, stress fish, reduce reproductive success, inhibit smoltification, contribute to susceptibility to disease, and alter competitive dominance (NMFS 2016b). Absence of large wood has contributed to lack of floodplain and channel structure and, along with declines in beaver abundance, has reduced pool habitats utilized by juvenile coho for shelter and thermal refugia throughout the SONCC ESU.

NMFS (2014e) released a final recovery plan for SONCC coho salmon that identified ten stresses, or limiting factors, and 13 threats to various life-stages for coho in the Upper Rogue River population. Limiting factors or stresses that were determined to be very high to all life stages (see table 32-1 in NMFS 2014e) included 1) altered hydrologic function primarily due to reservoirs constructed to support irrigated cropland and ground water depletions for a variety of uses, and 2) impaired water quality, especially high water temperatures (from lower water flows and removal of riparian trees) with lower dissolved oxygen. Other stresses with high or very high severity effects to multiple life stages (from fry to adults) include 3) degraded riparian forest conditions caused by removal of large conifers, channelization, wetland drainage, and other alterations, ,4) lack of floodplain and channel structure (channelization and reduction of slow, cool edgewater habitats where coho fry and juveniles thrive), and to a lesser extent, 5) altered sediment supply from roads, timber harvest, and bank erosion following removal of riparian vegetation causing elevated fine sediment input (NMFS 2014e). In addition, barriers to upstream migrations by small temporary agricultural dams, large diversion dams, and seasonal loss of stream flow in tributaries such as Trail Creek are a key limiting factor for the population.

Threats to all life stages having very high or high severity rankings contribute to the limiting factors discussed, above. Severe threats to the Upper Rogue River population include 1) agricultural practices that include water withdrawals causing insufficient in-stream flows along with effects due to grazing, wetland filling, riparian removal, channel simplification, and chemical application, 2) roads and high road densities that cause chronic fine sediment and increase probabilities of landslides, 3) urban-residential-industrial developments that have led to channelization, increased non-point source storm water pollution, and resulted in loss of aquatic system function, 4) channelization-diking that has impaired floodplain functions, constricted channels, and reduced surface-groundwater connections, all of which adversely affect water temperatures and salmon carrying capacities, 5) timber harvest that has caused early seral stage forests and high road densities in riparian zones, 6) dams and diversions that impede upstream adult salmon passage or strand downstream-migrating juveniles, if fish screens are not in place, 7) channelization and confinement of mainstem and tributaries to the Upper Rogue River that diminish summer and winter habitat carrying capacity for coho, and 8) climate change that is projected to cause increased regional average temperatures over the next 50 years and is currently leading to ocean acidification, affecting numerous marine habitat conditions including prey availability (NMFS 2014e).

BLM and Forest Service evaluated habitat conditions in the four 5th field watersheds crossed by the Pipeline wherein SONCC ESU coho salmon inhabit waterbodies (see table 3.5.3-1). Summaries for three of these watershed analyses are provided in appendix B.3 of PCGP's Resource Report 3 (table B.3-1h, table B.3-1i, and table B.3-1j). In these three watersheds, streams lacked in-stream LWD, fish access was limited, sedimentation was excessive, and high flows degraded in-stream habitats. More recently, the Little Butte Creek Watershed Council conducted an assessment in 2003 and the Upper Rogue Watershed Association's assessment was done in 2006 (table 3.5.3-1). Both assessments relied, in part, on ODFW stream habitat data that are also analyzed below in section 3.5.3.2 (see table 3.5.3-8). Findings in the more recent assessments were consistent with the earlier BLM and Forest Service watershed assessments: overall lack of complex pools and LWD in lower reach channels. However, NMFS (2016b) noted improvements for fish access to upstream habitats in the Upper Rogue sub-basin, including the removal of three diversion dams on the main-stream Rogue River – the Gold Hill Dam removed in 2008, the Savage Rapids Dam in 2009, and the Gold Ray Dam in 2010.

Big Butte Creek	● Lower Big Butte Watershed Analysis (BLM 1999d)	
Little Butte Creek	● Little Butte Creek Watershed Analysis (BLM and Forest Service 1997a).	● Little Butte Creek Watershed Assessment (Little Butte Creek Watershed Council 2003)

Historically, the SONCC coho salmon ESU inhabited the Upper Klamath Basin, upstream from Iron Gate Dam to Spencer Creek, but various impediments to passage, principally hydroelectric projects, have occurred due to basin development activities, reducing access to these areas. Currently, the Upper Klamath River coho salmon population is not viable and at high risk of extinction according to the population viability criteria. Summer and winter rearing habitat is in poor condition in many areas and is limited in its extent and connectivity. Mainstem conditions during the summer are prohibitive for migration and rearing, and hatchery influences on the population are very high. The removal of the four mainstem Klamath River dams, Iron Gate, Copco 1, Copco 2, and J.C. Boyle dams, up to Keno Dam—would be the most significant action that can be taken to restore the viability of the Upper Klamath population unit. (NMFS 2014e). Until that occurs, the Upper Klamath River population of SONCC coho persists in about 64 miles of mainstem habitat and numerous tributaries downstream from the Iron Gate Dam to Portuguese Creek in California (NMFS 2014e).

In 2008 the Oregon Fish and Wildlife Commission approved a plan to initiate efforts to re-establish anadromous fish into the Oregon portion of the Klamath River Basin. Although there is no definite timetable, this could result in the ESA-listed SONCC coho salmon being present in the Klamath River system upstream from Keno Dam, at some point in the future. Actual introduction would be unlikely to occur prior to Pipeline construction.

Species Recovery

NMFS (2014e) released a final recovery plan that addressed limiting factors and threats to each coho population within the SONCC ESU, including those within the Upper Rogue River population (see discussion under Threats, above). The plan calls for immediate habitat restoration and threat reduction in areas currently occupied by coho salmon in Evans, Trail, Elk, Big Butte, and Little Butte creeks. The greatest factor limiting the recovery of coho salmon in the Upper Rogue River is the lack of suitable rearing habitat for juveniles (NMFS 2014e). Consequently, recovery actions to create and maintain juvenile rearing habitat must be restored by restoring flow, increasing habitat complexity within the channel, restoring off-channel rearing areas, and reducing threats to in-stream habitat.

The following actions have been proposed: 1) reconnecting channels with floodplains, 2) increasing channel complexity, 3) improving flow timing and volumes, 4) improving fish access, 5) improving large wood recruitment, bank stability, shading, and food subsidies, 6) reducing predation and competition from non-native fish species, 7) improving estuarine habitat, 8) managing fisheries consistent with recovery of SONCC coho salmon, 9) managing scientific collection consistent with recovery of SONCC coho salmon, 10) tracking population abundance, spatial structure, productivity, or diversity, 11) tracking habitat condition, 12) reducing delivery of sediment to streams, and 13) reducing pollutants.

Life History, Habitat Requirements, and Distribution

Five life phases are generally recognized for the coho salmon: juvenile rearing, juvenile migration, growth and development, adult migration, and spawning. Juvenile summer and winter rearing areas and spawning areas are often located in small headwater streams. Juvenile migration corridors, adult migration corridors, and spawning areas are found in tributaries as well as main-stream reaches and estuarine zones. Growth and development to adulthood happens primarily in near- and offshore marine waters. Final maturation takes place in freshwater tributaries when the adults return to spawn (NMFS 2014e). Typically, coho salmon begin their spawning migration at 3 years old in late summer and fall and spawn by mid-winter. Eggs incubate for 1.5 to 4 months and then hatch. Juveniles rear for about 15 months in freshwater before migrating in spring to the ocean. They generally spend two growing seasons within the ocean before migrating back to their natal stream to spawn (NMFS 2014e).

Adult coho salmon rarely migrate farther up freshwater streams greater than 150 miles and generally return to spawn at sites where they hatched. Returning to parental spawning grounds ensures repeated use of suitable redd sites (Sandercock 1991). Straying (movements in non-natal stream systems) has been documented. In streams with deteriorated habitat such as low water flow, straying rates up to 50 percent have been documented (Sandercock 1991).

Preferred water temperatures during adult coho salmon upstream migration range between 7.2°C and 15.6°C (45°F to 60°F) with an upper lethal limit for adult coho salmon of 25.8°C or 78°F (Table 3 in Laufle et al. 1986). Preferred coho salmon spawning temperatures range from 4.4°C to 9.4°C (40ºF to 49ºF) while temperatures between 4.4°C to 13.3°C (40°F to 56°F) during egg incubation are preferred; the warmer the temperature, the less time before eggs hatch. The preferred range for juvenile survival systems is between 11.8°C to 14.6°C (53°F to 58°F) (Laufle et al. 1986). Elevated temperatures in streams may lead to early smoltification and ultimately premature migration towards sea during unfavorable conditions for young coho salmon (McMahon 1983).

Productive coho salmon streams are those that have a riffle-to-pool ratio of close to 1:1. Smaller streams are preferred over larger rivers due to the higher proportion of slack water to midstream area (Sandercock 1991). Substrate composition and riffles are factors, along with terrestrial vegetation, that are important for producing aquatic and terrestrial insects, which are food for coho salmon. Benthic invertebrate production is best in rubble, followed by bedrock, gravel, and sand. Coho salmon parr abundance is greatest in larger deeper pools where they can find cover near the streambank from logs, roots, debris, undercut banks, and overhanging vegetation (McMahon 1983).

Adult coho salmon require minimum water depths of 0.18 meter or 7 inches (Laufle et al. 1986) during upstream migration. Redd sites are found in waters at least 15 cm (5.9 inch) deep, though once hatched, coho salmon fry and parr prefer water at least 0.30 meter (1 foot) deep (McMahon 1983). During adult migrations upstream to spawn, water velocities less than 2.44 meters per second (m/sec; 8 feet/sec) are most desirable. At spawning grounds, coho salmon select redd sites where flows range between 5.0 and 6.8 m^3/minute (177 to 240 cubic feet per minute [ft^3/minute] or from 3 to 4 cfs), and where stream width does not exceed 1 meter or 3.2 feet (Sandercock 1991). For adult migration upstream, DO concentrations exceeding 6.3 mg/l are preferred (McMahon 1983). Incubation of eggs is best near DO saturation concentrations, and weight gains by fry are maximized in water with DO concentrations between 4 and 9 mg/l (Laufle et al. 1986).

Spawning substrate is gravel size between 1.3 and 10.2 cm (0.5 to 4 inches) (Laufle et al. 1986). Gravels less than 16 cm (6.3 inches) account for 85 percent of redd sites (Sandercock 1991). Average coho salmon redd size is 2.8 m^2 (30 ft^2); the recommended area per spawning pair is 11.7 m^2 or 126 ft^2 (Laufle et al. 1986). Egg survival to fry emergence has a positive correlation with gravel sizes between 3.35 mm and 26.9 mm (0.13 to 1.06 inches). For successful fry emergence, not more than 15 percent of the substrate should be fine sediment (McMahon 1983) because higher concentrations of fines may lead to earlier fry emergence, smaller fry, and fry with more yolk (Sandercock 1991). Silt loads less than 25 mg/l are preferable for survival of eggs and juvenile coho salmon (Laufle et al. 1986).

Coho salmon diets in freshwater differ between locations and seasons, though young coho salmon feed mainly on aquatic and terrestrial insects, becoming more piscivorous as they grow (McMahon 1983). After emergence, fry feed mostly on various life stages of aquatic insects including dipterans (true flies), ephemeropterans (mayflies), plecopterans (stoneflies), and others as well as crustaceans and fish (Laufle et al. 1986). In the West Fork Smith River in Douglas County (Oregon), diets of juvenile coho salmon (from December through May) were mostly benthic invertebrates (larval dipterans, ephemeropterans, limnephilid caddisflies, and plecopterans), but also included salmon eggs, aquatic snails, salamanders, and terrestrial invertebrates (Olegario 2006).

Major rivers, estuaries, and bays known to support coho salmon within the range of the SONCC ESU include the Rogue River, Smith River, Klamath River, Mad River, Humboldt Bay, Eel River, and Mattole River (NMFS 1999b), of which the Rogue and Klamath Rivers are within the Pipeline area. Historically, SONCC coho inhabited the Upper Klamath Basin. However, construction of the Copco 1 Dam on the mainstem Klamath River in 1918, followed by construction of the Copco 2 Dam in 1925 and the Iron Gate Dam in 1962 created impassible barriers to anadromous fish. Prior to construction of the dams, anadromous fish including SONCC coho salmon potentially could utilize over 600 miles of spawning, incubation, and rearing riverine habitats upstream from Iron Gate Dam (Hamilton et al. 2005). The historical extent of coho salmon upstream from Iron Gate Dam is believed to be Spencer Creek (Hamilton et al. 2005), which would have coincided with the Pipeline if not for the downstream barriers.

Specific timings of life history phases for SONCC coho salmon within the Pipeline project area are shown in figure 3.5.3-1. Included are the Rogue River mainstem and Upper Rogue River tributaries from Marial Creek to Lost Creek. Evident in figure 3.5.3-1 is the general synchrony in life phases within the mainstem and tributaries. Peak occurrence of juvenile out-migration lasts longer in tributaries than in the mainstem. In general, adult coho migrate upstream beginning in September and October and spawn during November through January. Fry emergence occurs about one month after spawning, and juvenile rearing continues throughout the year with juvenile out-migration extending from February through early June.

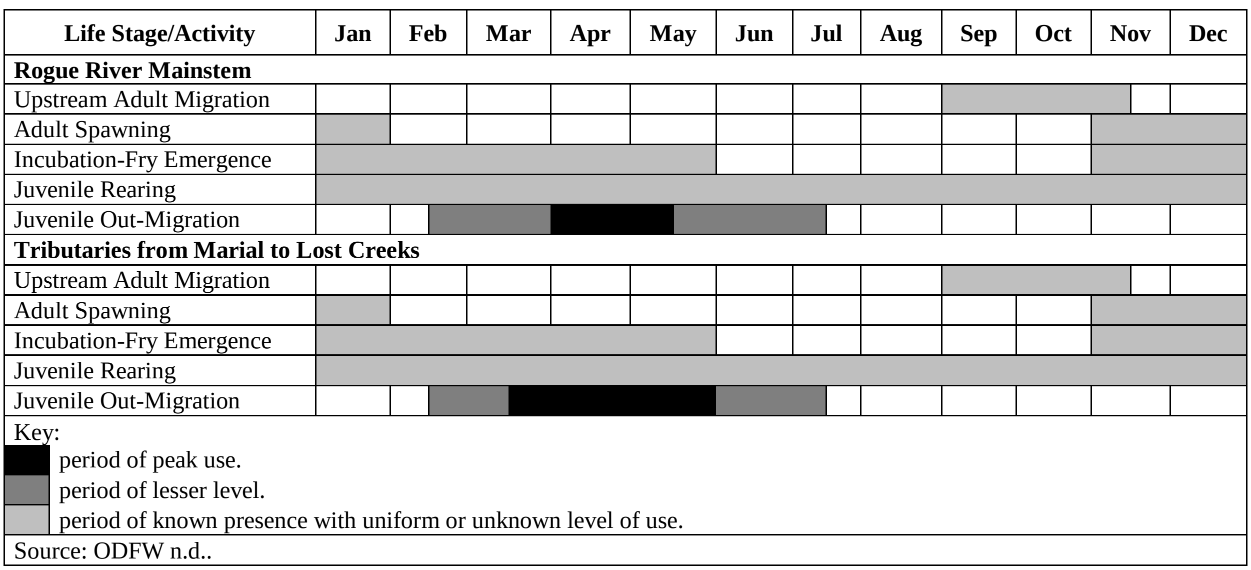

Figure 3.5.3-1 Approximate Timing of SONCC ESU Coho Salmon Use of the Rogue River Mainstem and Tributaries from Marial to Lost Creek

Coho in the SONCC ESU inhabit waterbodies in the following four fifth-field watersheds in the Upper Rogue Subbasin that would be crossed by the Pipeline: Trail Creek (HUC 1710030706), Shady Cove-Rogue River (HUC 1710030707), Big Butte Creek (HUC 710030704), and Little Butte Creek (HUC 1710030708). Table 3.5.3-2 summarizes the number of waterbodies within each fifth-field watershed crossed by the Pipeline that are known or assumed to support SONCC coho. Critical habitat is designated to include all river reaches accessible to listed coho within the range of the SONCC ESU. Critical habitat consists of the water, substrate, and adjacent riparian zone of estuarine and riverine reaches in hydrologic units and counties identified in NMFS 1999b, including the Upper Rogue HUC 1700307. Accessible reaches are those within historical range of the ESUs that can still be occupied by any life stage of coho salmon. Consequently, waterbodies with critical habitat enumerated in table 3.5.3-2 include those in which coho juvenile-fry are assumed to occur.

Population Status

At the time NMFS proposed this ESU for listing, population estimates for naturally reproducing coho salmon in the SONCC ESU included escapement records from Gold Ray Dam on the upper Rogue River as well as some catch estimates from all Oregon rivers and estimates of run size in the Rogue River. During the 1940s, 2,000 adult coho salmon were counted at the Gold Ray Dam per year, but that number declined to fewer than 200 adults in the early 1970s (NMFS 1995). The Gold Ray Dam on the Rogue River was removed in August 2010. Prior to dam removal, ODFW (2012b) counted adult coho and other anadromous salmonids passing the Gold Ray Dam as they utilized a fish ladder between late September and January, with last recorded counts before removal in June 2010. Abundance of coho returning to the Upper Rogue River above Gold Ray Dam increased from 1996 to 2002 but significantly declined from 2002 through 2009, the last full year counted before the dam was removed (see figure 3.5.3-2).

Similar declines were demonstrated with counts made at Huntley Park, at RM 8 on the lower Rogue River over a similar period, using daily totals of seine counts from 1997 to 2016 (ODFW 2002 to 2017e). ODFW has been monitoring spawner abundance on a regular basis on the Rogue River by seine estimates conducted in the vicinity of Huntley Park. Numbers of coho counted at Huntley Park represent salmon in the Illinois, Middle, and Upper Rogue populations aggregated together. From 1980 to 2004, the trend for adult spawner abundance on the Rogue River consistently increased (Spence et al. 2005), mostly due to decreased harvest. However, the overall trend since 2004 has been decreasing but increased returns have been observed through 2016, suggesting some improvement in run status from the lows of 2008 (see figure 3.5.3-3. A similar trend was observed for Rogue River coho adults (wild and hatchery, combined) migrating upstream past Huntley Park, downstream from the Gold Ray Dam location on the Rogue River. The data from Huntley Park indicate a severe decline from 2002 through 2008 (only 572 total coho counted) with an increasing trend (not significant) from 2008 through 2016 in figure 3.5.3-3 (ODFW 2017e).

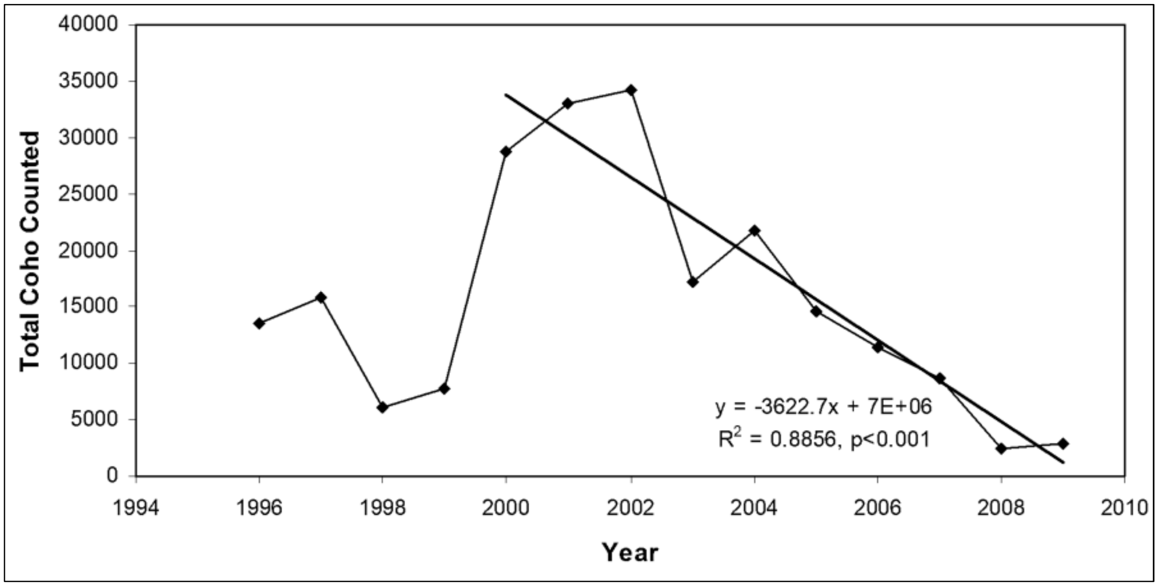

Figure 3.5.3-2 Total Number of SONCC Adult Coho Counted at the Gold Ray Dam Fish Ladder on the Middle Rogue River, from 1996 to 2009. The decreasing trend from 2001 through 2009 is significant (data from ODFW 2012b)

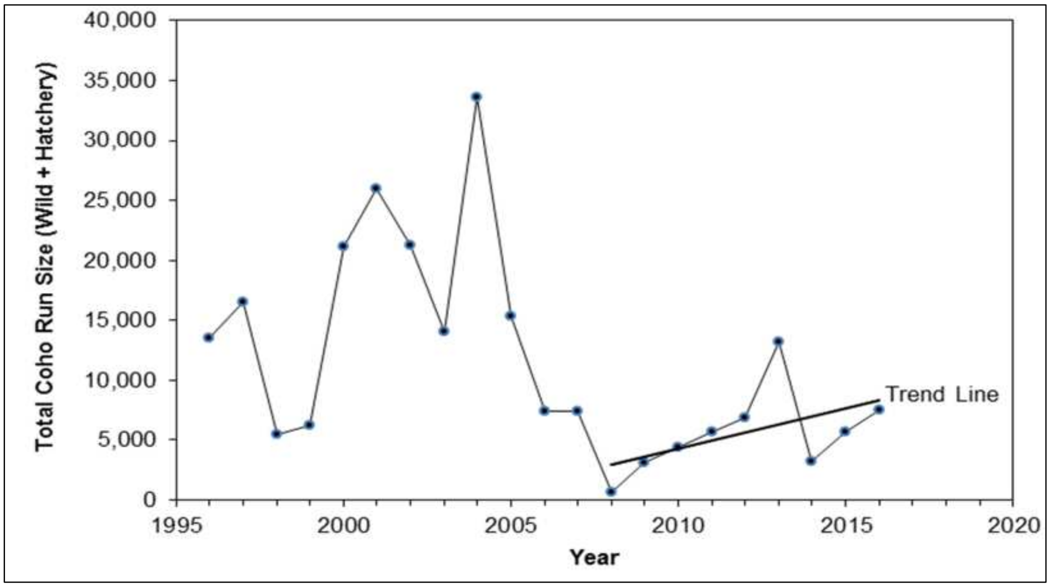

Figure 3.5.3-3 Total Number of SONCC Coho (Wild plus Hatchery-raised) Counted at Huntley Park (RM 8) on the Rogue River, from 2000 to 2016. The increasing trend from 2008 to 2016 (solid line) is not significant (data from ODFW 2017e)

Critical Habitat

Critical habitat for coho salmon in the SONCC ESU has been designated (NMFS 1999b) based on species' requirements such as space for growth and behavior, nutritional and physiological requirements, cover and/or shelter, reproduction sites, and habitats that are protected from disturbance or are representative of historically known population sites (NMFS 1999b). Other known essential physical and biological features considered essential for the conservation of the species, referred to as PCEs, are crucial to species conservation and critical habitat. These features include, but are not limited to, spawning sites, food resources, water quality and quantity, and riparian vegetation (NFMS 1999b).

Generally, riparian areas form the basis of healthy watersheds and impacts on them in turn affect these PCEs (NMFS 1999b). However, the PCEs that create healthy salmonid habitat vary throughout the coho salmon's range and the extant of the adjacent riparian zone may change accordingly. A site-potential tree height is a suitable benchmark for identifying a riparian zones in some cases, but in order to better assess the features of a specific locale, site-specific analyses provide the best means to characterize the riparian zone (NMFS 1999b). Spence et al. (1996) concluded that fully protected riparian management zones of one site-potential tree would adequately maintain 90 to 100 percent of most key riparian functions of Pacific Northwest forests (NMFS 1999b). Within that distance riparian zones provide the following functions: shade, sediment, nutrient or chemical regulation, streambank stability, and input of large woody debris or organic matter.

Critical habitat for coho salmon in the SONCC ESU includes the accessible reaches of all rivers (including water, substrate, and adjacent riparian zone of estuarine and riverine reaches) between the Mattole River in California and the Elk River in Oregon. Within the counties traversed by the Pipeline, critical habitat has been designated in USGS hydrologic unit Middle Rogue (HUC 17100308 – Jackson County) up to the Emigrant Lake Dam/Emigrant Lake; hydrologic unit Upper Rogue (HUC 17100307 – Jackson, Klamath, and Douglas Counties) up to the Agate Lake Dam/Agate Lake, Fish Lake Dam/Fish Lake, Willow Lake Dam/Willow Lake, and Lost Creek Dam/Lost Creek Reservoir; hydrologic unit Applegate (HUC 17100309 – Jackson County) up to Applegate Dam; and hydrologic unit Upper Klamath (HUC 18010206 – Jackson County) up to Irongate Dam (NMFS 1999b). The Pipeline would cross designated critical habitat within waterbodies of the Upper Rogue (HUC 17100307) hydrologic unit below the Lost Creek, Willow Creek, and Fish Lake Dams (NMFS 1999b). Eight waterbodies within the four fifth-field watersheds crossed by the Pipeline are known to support designated critical habitat for SONCC coho; five others are assumed to support SONCC ESU coho and are included as critical habitat in table 3.5.3-2.

3.5.3.2 Environmental Baseline

Analysis Area

Two analysis areas are applicable to coho salmon in the SONCC ESU: the marine analysis area and the riverine analysis area. The marine analysis area extends approximately 15 nmi offshore to the continental shelf. Within the marine analysis area, effects to coho salmon in coastal marine waters would be associated with LNG vessels entering and exiting the Port of Coos Bay from the Pacific Ocean.

The riverine analysis area includes two components: 1) the water column and substrate of all waterbodies crossed by the Pipeline within the Upper Rogue River watershed, from the point of crossing to the extent downstream where water quality is not adversely affected by suspended sediments generated during construction; and 2) riparian zones associated with waterbodies crossed by the Pipeline within the Upper Rogue River watershed affected in the short-term during construction and in the long-term by operation. Riparian zones widths are defined as the distance from each bank extending to one site-potential tree height.

The downstream extent of the riverine analysis area was determined by estimating the likely downstream extent that any stream crossing generated suspended sediment could equal ambient conditions within the Project area streams. The methods used to estimate this distance are explained below.

Total suspended solid (TSS) concentrations generated during wet open-cut construction have been estimated from models developed by Reid et al. (2004). Amounts of TSS produced during dry open-cut construction (fluming, dam-and-pump) adjustments are fractions of the concentrations produced during wet-open cuts (Reid et al. 2004). Estimates of TSS produced during dry open-cut construction across waterbodies in fifth-field watersheds are presented below in section 3.5.3.3. Average sediment percentages (grain sizes including gravel, sand, silt, and organics) for streams within each fifth-field watershed (see table 3.5.3-12 below in section 3.5.3.3 under Habitat and section 3.5.3.3 under Suspended Sediment by Pipeline Crossing Methods) were assumed to be fractions of the TSS generated during construction, and concentrations of each grain class at various distances downstream were estimated using a simple sediment transport model (Ritter, 1984). Distances at which concentrations near zero (settle out of suspension) differ considerably for the different grain sizes and are dependent on water depths and stream discharge rates at the time of construction (see table 3.4.3-17 and table 3.5.3-19 below in section 3.5.3.3 under Suspended Sediment by Pipeline Crossing Methods). Downstream settling distances would be much greater for deeper waterbodies with higher flow velocities than for shallow, slow flowing streams.

Using models noted above and data on the average sediment composition, stream depth, and average summer low flows for streams within range of SONCC coho that would be crossed by the Pipeline, the average downstream distance expected to be near assumed ambient concentrations of 2 mg/l of silt (0.0016 cm diameter, 0.023 cm/sec settling velocity) ranges from 699 meters (2,293 feet) in the Big Butte Creek Watershed to 1,235 meters (4,051 feet) in the Trail Creek Watershed. The average downstream distance expected to near assumed ambient concentrations of 2 mg/l of clay (0.0004 cm diameter, 0.0015 cm/sec settling velocity) ranges from 10,563 meters (34,647 feet) in the Big Butte Creek Watershed to 18,591 meters (60,978 feet) in the Trail Creek Watershed. These estimates are for average summer low flows likely to occur during construction within the ODFW (2008) allowed in-stream construction period. The estimated average downstream distance traveled of these very fine particles is a reasonable conservative limit to consider for the analysis area. The riverine analysis area for SONCC coho salmon has been conservatively estimated to distances ranging from 34,647 feet to 60,978 feet (6.6 to 11.5 miles) downstream from the point of crossing within the affected fifth-field watersheds in the range of SONCC coho salmon (see figure 3.5.3-4).

Species Presence

Coho salmon in the SONCC ESU are known or are expected to occur within the Upper Rogue River Hydrologic Unit (HUC 17100307) in some perennial and intermittent tributaries. The Pipeline would cross four fifth-field watersheds including Trail Creek (HUC 1710030706), Shady Cove-Rogue River (HUC 1710030707), Big Butte Creek (HUC 1710030704), and Little Butte Creek (HUC 1710030708). All affected waterbodies within the Upper Rogue Subbasin and within the range of SONCC coho salmon ESU proximate to the Pipeline are included in table 3.5.3-3. There are 90 waterbodies included in the table, of which 14 are perennial, 73 are intermittent, and three are ponds. Coho salmon are known to occur in eight of the waterbodies and are assumed to be present in three others based on connectivity to perennial streams known to support coho salmon, the presence of steelhead and/or resident salmonids, and/or information provided by fisheries biologists. Data in table 3.5.3-3 were revised based on ODFW (2017f) fish habitat distribution shapefiles and Oregon Department of Forestry (ODF 2018) Forest Practices statewide hydrography shapefiles that provide field evaluations for fish presence/absence in stream segments.

a/ Dry open-cut crossing methods include flume or dam-and-pump procedures. Dam-and-pump methods would be utilized where streambed blasting is anticipated to eliminate blasting around the flume. The dam-and-pump crossing method is the preferred crossing procedure in steep incised drainage valleys where worker safety may be compromised when placing ("threading") the pipe string under the flume pipe and where there is a risk of upsetting the flume during this operation. The dam-and-pump crossing method is also the preferred crossing method on small streams under low flow conditions during the ODFW-recommended in-water work period. PCGP proposes temporary/short-term fish passage restriction when completing dam-and-pump crossings within the ODFW-recommended in-water work period. Appendix M provides details of stream crossings.

b/ ODFW 2017f; ODF 2018

c/ Assumes fisheries construction windows only apply to those waterbodies flowing at the time of construction and windows do not apply to HDD crossings.

d/ Streambed bedrock based on PCGP's Wetland and Waterbody delineation surveys. Streambed bedrock may require special construction techniques to ensure pipeline design depth. Special construction techniques may include rock hammering, drilling and hammering, or blasting. The need for blasting would be determined by the construction contractor and would only be initiated after ODFW blasting permits are obtained.

In-stream construction of the Pipeline would occur before most SONCC coho begin upstream migration and spawning by adults (see figure 3.5.3-1). However, juvenile coho are expected to be rearing in many of those streams at the time of construction. Although there are no data on numbers of juveniles expected to be present in streams crossed by the Pipeline, the following estimation procedure was developed after an estimate for numbers of juveniles present in streams crossed was requested by NMFS (2015e).

Total stream miles occupied by coho salmon within the 4th Field HUCs in table 3.5.3-4 and each of the 5th Field HUCs crossed by the Pipeline in range of SONCC coho were derived with GIS by combining shapefiles of ODFW Fish Distribution data (ODFW 2017f) with watershed shapefiles from National Hydrography Dataset (USGS 2016). Stream miles with coho spawning habitats and coho rearing habitat in the range of SONCC coho were similarly derived; stream miles in those habitats were added to provide Stream Miles for Juvenile Fry Presence in table 3.5.3-4.

TABLE 3.5.3-4

Total Stream Miles with SONCC Coho Habitats in 4th Field and 5th Field Watersheds and Estimates of Streams with Juvenile Fry Coho.

Subbasin and Fifth-Field Watersheds	Total Stream Miles with Coho in HUC a/	Stream Miles with Spawning Habitat	Stream Miles with Rearing Habitat	Stream Miles for Juvenile Fry Presence b/
Upper Rogue Subbasin	**197.88**	**184.00**	**5.47**	**189.46**
Trail Creek	17.15	16.96	0.19	17.15

Little Butte Creek	60.95	60.95	0	60.95

a/ Total Stream Miles with Coho in HUC includes miles of Historical, Migration, Rearing, Spawning, and Unknown habitats.
b/ Stream Miles for Juveniles' Presence is the sum of Stream Miles for Spawning and Rearing Habitats in HUC
Source: StreamNet 2012; ODFW 2017f.

Numbers of redds and spawning adult coho salmon counted in fourth field watersheds over time are available on the StreamNet (2012) Database accessed through the ODFW Natural Resources Information Management Program. Only 20 spawning surveys were conducted within fifth field watersheds crossed by the Pipeline in range of SONCC coho. The most recent survey was conducted in 1999. In addition, the database provided only one record of a redd survey for SONCC coho in the Upper Rogue Subbasin. With so limited information available, numbers of adult coho salmon (not including jacks or subadults) reported as peak live or dead fish were used to estimate numbers of juvenile fry present in streams that would be crossed by the Pipeline. Data for numbers of adults counted per mile from StreamNet Database are summarized in table 3.5.3-5, below.

TABLE 3.5.3-5

Results of Coho Spawning Surveys a/ Conducted in Streams Crossed by the PCGP Project

Subbasin and Fifth-Field Watersheds	Number of Surveys	Year(s)	Average Adults per Mile Surveyed	90% Confidence Interval

Big Butte Creek	0	N/A	0	0
Little Butte Creek	15	1996-1999	9.51	± 4.50
Source: StreamNet 2012.				

The following assumptions have been applied to the adult spawning data in the Upper Rogue River Sub-basin coinciding with SONCC coho and Pipeline waterbody crossings:

- The male:female ratio of live or dead spawners is 1:1 (Knudsen et al. 2003),
- At low to moderate densities of spawners, there is 1 redd for each female (Lestelle and Weller 2002);
- Redds are only present in stream reaches classified as spawning habitat by ODFW (2014c);
- The average number of eggs per redd is between 300 and 1,200 with 800-900 eggs being most frequent (Sandercock 1991)
- Under average conditions, 15-27 percent of all eggs would survive during incubation (mean of 27.1 percent survival was observed in Oregon coastal streams (Sandercock 1991);
- Juveniles utilize spawning habitats during rearing as well as rearing habitats as classified by ODFW (2014c). Juveniles distribute themselves in uniformly spaced territories regardless of presence of pools, riffles or runs in the natal stream.

With those assumptions applied to data from the Upper Rogue River in table 3.5.3-6, there would be an average of 4.08 redds per mile (± 1.58 redds per mile) within all spawning habitats in the Upper Rogue River Sub-basin. That estimate along with the estimate of stream miles of spawning and rearing habitats in HUCs, and the assumptions above for eggs per redd and egg survival rates were used to estimate numbers of Juvenile Fry per Mile of Habitat in table 3.5.3-6 for each of the 5th Field HUCs crossed within range of the SONCC ESU. Values for redds per mile with 90% confidence intervals were not carried through the analyses in table 3.5.3-6. In reality, estimates of Juveniles per Mile of Habitat would vary from year to year showing at least as much variability as the Total Coho Run Size counted at Huntley Park from 2000 to 2016, shown in figure 3.5.3-3, above.

There would be some mortality between juvenile fry and juvenile smolt stages and during the period from fry emergence (through the end of May) before pipeline construction (beginning June 15). Therefore, estimates are very conservative. Waterbodies within the Upper Rogue Subbasin would be crossed between June 15 and September 15. Based on figure 3.5.3-1, instream construction could coincide with portions of the juvenile coho out-migration periods during June and July. Potentially, there could be some post-winter pre-smolt juvenile coho present during construction. However, very few are expected because reported over-winter survival rates of juvenile coho are <40 percent, at least in waterbodies studied within the Coos Bay Frontal-Pacific Ocean 5th field watershed (Weybright and Giannico 2017).

Subbasin and Fifth-Field Watersheds	Total Redds in HUC a/	Total Eggs in HUC b/	Total Juvenile Fry Surviving in HUC c/	Juvenile Fry per Mile of Habitat d/
Upper Rogue Subbasin	751	638,100	172,925	913
Trail Creek	69	58,821	15,941	929
Shady Cove-Rogue River	125	106,047	28,739	810
Big Butte Creek	133	112,906	30,598	940
Little Butte Creek	249	211,369	57,281	940

a/ Total Redds in HUC = the Average Redds per Mile in 4th Field HUC multiplied by Stream Miles of Spawning Habitat in table 3.5.3-4.
b/ Total Eggs in HUC = average of 850 eggs per red (see assumptions) multiplied by Total Redds in HUC.
c/ Total Juvenile Fry Surviving in HUC = 27.1 percent average survival rate of eggs (see assumptions in text) multiplied by Total Eggs in HUC.
d/ Juveniles per Mile of Habitat = Total Juvenile Fry Surviving in HUC divided by Stream Miles of Juvenile's Presence in table 3.5.3-4.

Habitat

Existing conditions of aquatic habitats within the fifth-field watersheds in the Upper Rogue Subbasin that would be crossed by the Pipeline were evaluated with data collected by ODFW in their Aquatic Inventories Project (ODFW 2014c). In cooperation with other agencies, ODFW has conducted stream surveys throughout the state including streams within watersheds crossed by the Pipeline. Four types of habitat information can be used to deduce quantitative evaluations of the overall fish habitat condition within the fifth-field watersheds that would be crossed by the Pipeline: 1) pool habitat conditions, 2) riffle habitat conditions, 3) shade conditions, 4) woody debris habitat condition, and 5) riparian conifer habitat condition. ODFW (Foster et al. 2001) has developed benchmark criteria for each of these habitat conditions that would represent undesirable and desirable habitat conditions. The benchmarks are provided in table 3.5.3-7 along with the various aquatic habitat conditions to which they apply. The conditions of specific streams crossed by the Pipeline are assumed to be comparable to the average conditions for the sampled reaches in each of the corresponding four fifth-field watersheds. Compilations of ODFW stream-reach data (see appendix X) are summarized in table 3.5.3-8 for the four watersheds in the Pipeline project area occupied by SONCC coho. The percent of sampled stream reaches that are at or above desirable benchmark conditions and percent that are at or below undesirable conditions indicate the aquatic habitat conditions.

TABLE 3.5.3-7

Oregon Department of Fish and Wildlife Aquatic Inventory and Analysis Project Criteria for Aquatic Habitat Conditions and Benchmarks

Aquatic Habitat Condition	Benchmark Level for Condition	
	Undesirable	**Desirable**

Benchmark conditions are not absolute, but they provide a method for comparing values of key aquatic habitat components (Foster et al. 2001). Pools provide refuges for fish during high and low stream flows, slow water habitats for adults and juveniles, over-wintering habitat for some fish species, habitat during periods of low summer flows, and, those associated with large woody debris, provide habitat complexity. Riffles provide spawning habitats for various salmonid species that construct nests or redds in gravels of various sizes, specific to salmonid species. Sand, silt, and organic debris can reduce suitability of spawning habitats by filling pores between gravel particles that are necessary for intergravel stream flows, availability of oxygen, and development of embryos; high percentages of sand, silt, and organic material in riffles indicate poor conditions as spawning habitat.

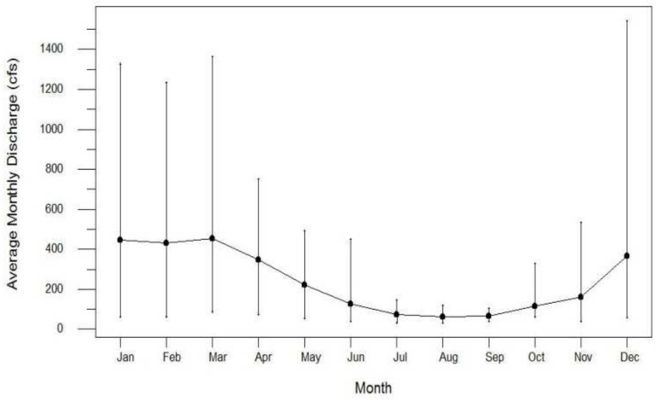
Riparian trees provide shade over stream channels which reduces deleterious effects of high summer water temperatures. Riparian vegetation stabilizes stream banks, contributes to development of bank undercutting (thermal and hiding cover), limits erosion and sedimentation from stream banks, and provides LWD as an important component of the aquatic habitat. LWD, especially contributed by riparian conifers, provides cover for fish, physical habitat complexity that influences stream flows and channel diversity, and biological complexity as substrates for macroinvertebrate communities that provide food for salmonids during different life stages (Foster et al. 2001).

BLM and Oregon Forest Industry Council surveyed 126 stream reaches in the four fifth-field watersheds within the Upper Rogue Subbasin that would be crossed by the Pipeline: 20 in the Trail Creek HUC 1710030706, 9 in the Shady Cove-Rogue River HUC 1710030707,41 in the Big Butte Creek HUC 1710030704, and 56 in the Little Butte Creek HUC 1710030708. Surveys were conducted during summers in different watersheds between 1994 and 1999.

For most of the stream reaches sampled in the four watersheds, habitat conditions related to pools (area, frequency, residual depths) were between moderate levels and desirable benchmarks. The majority of reaches were deficient in complex pools associated with LWD. Numbers of LWD pieces, LWD volume, and numbers of key pieces were below benchmark conditions in most stream reaches, which helps explain the poor state of pool complexity associated LWD. Related to low levels of LWD are the low numbers of large conifers (greater than 20 inches dbh) within sampled riparian zones. However, shade conditions are generally at moderate or desirable benchmark levels, primarily due to the narrow widths of most streams and the presence of broadleaf riparian red alders and cottonwoods that provide shade during summer months (Upper Rogue Watershed Association 2006).

In general, riffle habitat conditions are better than pool habitat conditions, but they are not at desirable conditions overall. For example, ratios of stream widths to depths in most stream reaches in the four watersheds were generally low, which indicates that streams are more narrow and deep than wide and shallow. Areas of gravel substrates were not at or above desirable benchmarks in most sample reaches, and areas of fine sediments in riffles generally exceeded the desirable benchmarks. However, some of this analysis is based on data from before the flood event of the winter of 1996-1997, and conditions could have changed significantly from what the data shows (Little Butte Creek Watershed Council 2003).

Monthly average stream discharges over the annual cycle are provided in figure 3.5.3-5 for two waterbodies within the Upper Rogue Subbasin, Big Butte Creek – a tributary to Rogue River with a 245 square mile watershed—and Elk Creek with a watershed area of 379 square miles.



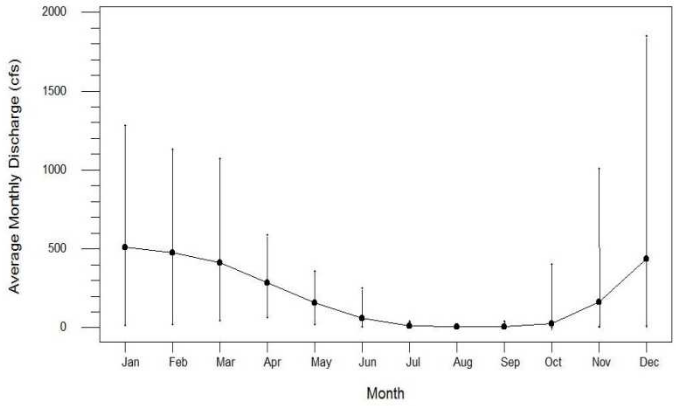


Figure 3.5.3-5 Average Monthly Discharge (cfs) in (A) Big Butte Creek (USGS Gage 14337500) from 1945 to 2016, and (B) Elk Creek (USGS Gage 1433800) from 1946 to 2015. Vertical lines show maximum and minimum discharges during the periods of record.

Monthly flows in the Upper Rogue River below Lost Creek Lake are heavily influenced by irrigation water withdrawals and are highly variable. Water is also diverted for use in hydroelectric power generation (Upper Rogue Watershed Association 2006). Monthly flows in Big Butte Creek and Elk Creek at the confluence with the Rogue River near Trail Creek were selected as representative because neither segment is influenced by dam releases for irrigation or hydropower. Precipitation falling as snow during winter months does not affect discharges until later in the year (April through May). Minimum flows tend to occur during June, July, August, and September. The ODFW (2008) in-stream construction window for Upper Rogue River and tributaries is June 15 to September 15, coinciding with low flows.

Critical Habitat

Critical habitat for coho salmon in the SONCC ESU (NMFS 1999b) includes "all waterways, substrate, and adjacent riparian zones below longstanding, naturally impassable barriers (i.e., natural waterfalls in existence for at least several hundred years)." The Pipeline crosses designated critical habitat associated with waterbodies in the Upper Rogue Subbasin (HUC 17100307), below the Lost Creek, Willow Creek, and Fish Lake Dams. Essential features of coho salmon critical habitat in those waterbodies include adequate 1) substrate, 2) water quality, 3) water quantity, 4) water temperature, 5) water velocity, 6) cover and shelter, 7) food, 8) riparian vegetation, 9) space, and 10) safe passage conditions (NMFS 1999b).

Critical habitat for SONCC coho salmon is designated based on species requirements such as space for growth and behavior, nutritional and physiological requirements, cover and/or shelter, reproduction sites, and habitats that are protected from disturbance or are representative of historically known population sites (NMFS 1999b). Additionally, NMFS uses other known essential physical and biological features that are crucial to species conservation and critical habitat including spawning sites, food resources, water quality and quantity, and riparian vegetation (NFMS 1999b). Activities that may affect critical habitat and PCEs include, but are not limited to, timber sales, road building, mining, dredge and fill, and bank stabilization activities (NMFS 1999b).

Generally, riparian areas form the basis of healthy watersheds, and impacts on them in turn affect these PCEs (NFMS 1999b). However, the PCEs that create healthy salmonid habitat vary throughout the coho salmon's range, and the extant of the adjacent riparian zone may change accordingly. A site-potential tree height is a suitable benchmark for identifying a riparian zone in some cases, but in order to better assess the features of a specific locale, site-specific analyses provide the best means to characterize the riparian zone (NFMS 1999b).

Riparian areas provide the following functions: shade, sediment, nutrient or chemical regulation, streambank stability, and input of LWD or organic matter. In addition, critical habitat includes inaccessible headwater or intermittent streams which provide key habitat elements (e.g., LWD, gravel, water quality) crucial for coho salmon in downstream reaches (NMFS 1999b). Widths of adjacent riparian zones may vary by site-specific and/or landscape characteristics, but a distance of one site-potential tree height serves to define riparian zone widths in some cases (NMFS 1999b). With these considerations, all perennial and intermittent streams in table 3.5.3-3 are included in critical habitat within the riverine analysis area and have been summarized in table 3.5.3-9.

No specific geographic data have been developed for SONCC coho salmon critical habitat. Consequently, waterbodies identified with coho presence by ODFW (2014c) were assumed to provide critical habitat for SONCC coho, which includes suitable habitat believed to be used currently or historically by wild, natural, and/or hatchery coho fish populations. Additionally, ODFW winter steelhead GIS layers were reviewed and, if spatially near waterbodies crossed or adjacent to the Pipeline project, were included as "assumed" coho presence. These data were combined with distributions of SONCC coho in California (UC Davis Center for Watershed Sciences 2016). With distributions in Oregon and California, combined, there are 108 fifth field watersheds occupied by SONCC covering a total 16,423 square miles with 3,578 stream miles of current and/or historically occupied habitat. Absent any other information, critical habitat for SONCC coho is assumed to coincide with the total stream miles. Approximately 5.5 percent of stream miles with critical habitat for the SONCC coho ESU is within the Upper Rogue Subbasin and 4.1 percent is in the four fifth field watersheds crossed by the Pipeline. Eight waterbodies within the four fifth-field watersheds crossed by the Pipeline are known to support designated critical habitat for SONCC coho; five others are assumed to support SONCC ESU coho and are included as critical habitat in table 3.5.3-2.

3.5.3.3 Effects of the Proposed Action

Analyses of effects are addressed separately for the marine analysis area and riverine analysis area for the SONCC coho salmon ESU.

Direct and Indirect Effects – Marine Analysis Area

Potential project-related effects to SONCC coho salmon within the marine analysis area include: 1) acoustic effects to coho from LNG carriers transiting the marine analysis area, and 2) oil and gas spills from LNG carriers at sea.

Acoustic Effects

Underwater noise may affect coho salmon in the SONCC ESU. LNG carriers transiting the marine analysis area would produce underwater noise. LNG carriers built in 2003 with 138,028 m^3 capacity were reported by Hatch et al. (2008) to produce sound levels (with 1 standard error) of 182 ± 2 dB re: 1 µPa @ 1 meter. Underwater noise levels are expected to vary by ship type and also by carrier length, gross tonnage, carrier speed, and, to some extent, carrier age—older carriers tended to be louder than newer carriers. Based on the general trend for higher underwater noise generated by larger carriers (McKenna et al. 2012), it is possible for some of the LNG carriers that would utilize the LNG Terminal to generate more noise than the LNG tanker built in 2003 with 138,028 m^3 capacity reported by Hatch et al. (2008) that produced sound levels (with 1 standard error) of 182 ± 2 dB re: 1 µPa @ 1 meter.

It is likely that any LNG carrier noise generated in the marine analysis area would be below thresholds for adverse effects to fish with the possible exception of those fish very near the hull for extended periods, which would be an unlikely event. The criteria for noise levels considered harmful to fish are presented above in the green sturgeon discussion (see section 3.5.1), but generally values less than 183 dB are not considered harmful to fish. As a result, only fish within about one meter (three feet) of the vessel would be in danger of direct noise harm. Noise from LNG carriers would likely increase the background noise within the marine analysis area, which is occurring globally (Slabbekoorn et al. 2010). While background levels are not specifically known in the marine analysis area, analyses of more recent vessel-traffic related noise shows that such levels along the US west coast are holding steady or increasing slightly offshore from Southern California but decreasing in the area off Oregon and Washington (Andrew et al. 2011). SONCC coho salmon would be highly unlikely to be within three feet of these vessels, and thus adverse effects to SONCC coho from LNG carrier noise are not expected.

Fuel or Oil Spills at Sea

Fuel (e.g., diesel) used for LNG carrier propulsion or oil used for mechanical equipment could possibly leak or be spilled while LNG vessels are en route in the waterway. The low amount of petroleum products on LNG carrier greatly reduces the chance of impacts in the marine environment from petroleum spills. The Federal Water Pollution Control Act, as amended by the CWA (33 U.S.C. 1251–1387), prohibits the discharge of oil upon the navigable waters of the U.S. LNG carriers calling on the LNG Terminal would also be required by the U.S. Coast Guard to have a vessel response plan in order to be adequately prepared for accidental spills. Therefore, neither fuel nor oil leaks from LNG vessels transiting in the waterway to and from the LNG Terminal are likely to have adverse effects on aquatic resources including coho salmon.

Direct and Indirect Effects – Riverine Analysis Area

The Pipeline would cross 13 waterbodies known or presumed to be inhabited by coho salmon in the SONCC ESU (see table 3.5.3-2). Effects could occur from freshwater in-water construction activities, terrestrial/riparian habitat modification, accidental spills or leaks of hazardous materials, and periodic maintenance of the Pipeline. Construction of the Pipeline project could directly and/or indirectly affect SONCC coho salmon and critical habitat through one or more of the following pathways:

- interference with key life history functions for native species;
- acoustic shock from blasting pipe trench through bedrock streambeds;
- underwater noise produced during use of a track hoe or impact hammer if fish are proximate to the construction site;
- suspended sediment (turbidity) generated during construction across waterbodies can adversely affect coho and aquatic habitats;
- inadvertent release of drilling mud during HDD construction;
- movement blockage during in-stream construction;
- salvaging fish that are entrained and/or entrapped;
- removal of riparian vegetation that can reduce shade (which could increase water temperatures), limit streambank stability, and affect recruitment of LWD;
- effects to aquatic habitats including freshwater stream invertebrates;
- hydrostatic testing and risk of test water entering streams;
- introduction and/or re-distribution of aquatic nuisance species;
- accidental release of fuels and entry of other petroleum products into surface waters can adversely affect coho and other aquatic organisms;
- risk of channel migration, avulsion, widening, and/or streambed scour;
- effects to hyporehic exchange and hyporehic zones;
- run-off from new permanent access roads, new temporary access roads, existing access roads and temporary extra work areas;
- run-off from contractor yards, rock source and disposal sites, and aboveground facilities; and/or
- application of herbicides to control noxious weeds near waterbodies may adversely affect coho.

All affected waterbodies proximate to the Pipeline that are within the range of SONCC coho salmon ESU are within the Upper Rogue River subbasin and four fifth-field watersheds. The route would include 72 direct waterbody crossings within the Upper Rogue River Subbasin (see table 3.5.3-3 and summarized below in table 3.5.3-10). Dry open-cuts using a flume would be utilized at 57 crossings if water is present at the time of construction. Blasting may be necessary for construction at 13 streams that would be crossed by dry open-cut methods (probably by dam-and-pump; see Pipeline project description in section 2.1.2) because the streambed of each is bedrock (see table 3.5.3-3 and table 3.5.3-10). An HDD crossing would be used at the crossing of the Rogue River (MP 122.7), and a conventional bore would be used at the Medford Aqueduct Ditch (MP 133.4). An additional 18 waterbodies summarized in table 3.5.3-10 would not be crossed by the Pipeline but are adjacent to the centerline in the right-of-way. Of the 90 waterbodies included in the table, 14 are perennial streams, 73 are intermittent streams, and 3 are ponds (see table 3.5.3-3, above).

TABLE 3.5.3-10

Proposed Pipeline Construction Methods for Crossing Waterbodies within
the Subbasin and Fifth-Field Watersheds Coinciding With the SONCC Coho Riverine Analysis Area

Subbasin and	**Number of Waterbodies with Construction Method**

Fifth-Field Watersheds	HDD or Direct Pipe	Bore	Wet Open-Cut	Diverted Open-Cut	Dry Open-Cut; Fluming	Dry Open Cut; Bedrock a/	Total Crossed	Adjacent Not Crossed b/
Upper Rogue Subbasin								
Trail Creek					4	2	**6**	2
Shady Cove-Rogue River	1				9	1	**11**	7
Big Butte Creek		1			3	5	**9**	3
Little Butte Creek					41	5	**46**	6
TOTAL	**1**	**1**	**0**	**0**	**57**	**13**	**72**	**18**

a/ Bedrock streambeds would be crossed by dry open-cuts (probably by dam-and-pump) but may require special construction techniques to ensure pipeline design depth including rock hammering, drilling and hammering, or blasting. The need for blasting would be determined by the contractor and would only be initiated after ODFW blasting permits are obtained.
b/ Waterbodies within the construction right-of-way that would not be crossed

Timing to Life History Functions

Waterbodies within the Upper Rogue Subbasin would be crossed between June 15 and September 15 (ODFW 2008), which partially coincides with adult upstream migrations of coho (see figure 3.5.3-1). In general, construction would be timed to miss periods of major juvenile or adult migrations and occur during low stream flows. The in-stream construction window coincides with coho juvenile rearing. Juvenile fry rear for about 15 months in freshwater before migrating in spring to the ocean. Consequently, juvenile fry present would likely be a combination of subadults from the previous year and juvenile fry several months old from the current year. Construction across waterbodies within the Upper Rogue Subbasin could occur during adult upstream migration, beginning in September, but would be completed before spawning in early November (see figure 3.5.3-1).

Acoustic Shock

There are 13 waterbody crossings within the SONCC coho ESU where shallow bedrock may occur, potentially requiring blasting and/or mounted impact hammers to construct a trench through bedrock substrates (see table 3.5.3-3 and summarized in table 3.5.3-10). Explosives detonated near water produce shock waves that can be lethal to fish, fish eggs, and fish larvae by rupturing swim bladders and addling egg sacs (British Columbia Ministry of Transportation 2000). Explosives detonated underground produce two modes of seismic waves: 1) body waves that are propagated as compressional primary (P) waves and shear secondary (S) waves; and 2) surface waves produced when a body wave travels to the earth surface and is reflected back (Alaska Department of Fish and Game - ADFG 1991). Shock waves propagated from ground to water are less lethal to fish than those from in-water explosions because some energy is reflected or lost at ground-water interface (ADFG 1991). Peak overpressures as low as 7.2 psi produced by blasting on a gravel/boulder beach caused 40 percent mortality in coho salmon smolts. Other studies revealed 50 percent mortality in smolts with peak overpressures ranging from 19.3 to 21.0 psi (ADFG 1991).

In 1991, the ADFG established a standard for blasting effects to anadromous fish that limited blast-induced overpressures in the water column. ADFG (1991) reported that a pressure change of 2.7 psi is the level for which no fish mortality occurs. ADFG (1991) calculated the straight line distances for a single shot explosive charge of given weight through rock and other materials to dissipate to an overpressure standard of 2.7 psi (non-lethal pressure for anadromous fish). Typical trench blasting scenarios use multiple 1- to 2-pound charges separated by an 8-milisecond delay to excavate the trench. With use of 1- to 2-pound charges in rock, the setback distance (at which 2.7 psi would occur) from the blast trench to the fish habitat is between 34 and 49 feet (see Table 3, in ADFG, 1991).

New research (Dunlap, 2009) and an in-depth review (Kolden and Aimone-Martin, 2013) of empirical studies of the physiological effects of blasting on adult salmonids and embryos prompted ADFG to revise the blasting standard (Timothy, 2013):

> *"The instantaneous pressure rise in the water column in rearing habitat and migration corridors is limited to no more the 7.3 psi where fish are present. Peak particle velocities in spawning gravels are limited to no more the 2.0 in/s during the early stages of embryo incubation before epiboly is complete."*

Application of the new standard for 7.3 psi in equations in ADFG (1991) was used to derive setback distances from water for 2-pound charges in rock. Based on these calculations, a distance of about 26 feet would result in the avoidance of adverse effects to salmonids in water. The setback distance used in PCGP's Fish Salvage Plan (appendix T) added 25 feet to each side of the construction right-of-way, totaling at least 50 feet from the blasting location at the trench. Application of the new ADFG blasting standard for a 2-pound charge in bedrock would indicate that the current setback distance is more than adequate to ensure that any blasting that does occur will not adversely affect ESA-listed coho salmon and other salmonid species.

Several approaches have been suggested to reduce risk of injury or mortality to fish in closest proximity to blasting locations (Wright and Hopky 1998):

- deployment of bubble curtains/air curtains to disrupt the shock wave;
- deployment of noise generating devices, such as an air compressor discharge line, to scare fish away from the site; or
- removal or exclusion of fish from the work area before the blast occurs.

To reduce impacts on resources, PCGP developed a *Blasting Plan* that incorporates many of these recommendations. The plan states that PCGP does not anticipate any in-water blasting in any streams crossed by the Pipeline. However, blasting may occur in uplands adjacent to streams or within dry streambeds. In those situations, PCGP would attempt to minimize shock waves from blasting that may affect aquatic resources by the types of explosives selected, the size of charges, and the sequences of firing. In addition, bubble curtains may be used. The details of specific site blasting actions would be determined in coordination with managing resource agencies. Lastly, fish may be removed from the crossing area, in accordance with PCGP's *Fish Salvage Plan (*see Conservation Measures below*)*.

The *Fish Salvage Plan* is provided in appendix T. The plan includes measures to exclude fish and prevent them from re-entering isolated portions within waterbodies crossed for distances sufficient to avoid or minimize adverse effects by blasting bedrock in streambeds. The specific plans would be approved by the managing resource agencies. Prior to any blasting, proper permits would be obtained and agencies notified as required by permits.

Of the 13 waterbodies where shallow bedrock may occur, potentially necessitating blasting and/or mounted impact hammers used to construct a trench, only four are known to support SONCC coho: two in the Trail Creek watershed (West Fork Trail Creek at MP 118.9 and Canyon Creek at MP 120.5) and two in the Big Butte Creek watershed (Neil Creek at MP 132.1 and Quartz Creek at MP 132.8). Dry open-cut construction, most likely by dam-and-pump procedures, would be used to cross the four streams. At some waterbody crossing sites the right-of-way would be "necked down" to 75 feet; in others the construction right-of way would be full the 95-foot width. Fish would be salvaged from within the 75-foot or 95-foot wide right-of-way crossing of each stream. The fish salvage area would be isolated by sand bag dams installed upstream and downstream of the centerline. As described in the *Fish Salvage Plan* (see appendix T), fish would be excluded from an area larger than the limits of the construction right-of-way width, isolated by sand bags. If blasting is required, fish would be excluded from an additional 25 feet on each side of the construction right-of-way. The plan includes measures to exclude fish and prevent them from re-entering isolated portions within waterbodies crossed for distances sufficient to avoid or minimize adverse effects by blasting bedrock in streambeds.

Estimates of juvenile coho present at crossing sites in streams with bedrock substrates were based on the following assumptions: 1) all rights-of-way are 95 feet wide at each stream crossing within which coho would be salvaged, and 2) coho would be excluded from an additional 50 feet (a total of 145 feet of stream length) from the right-of-way edges (25 feet from each edge). Numbers of juvenile coho potentially present or assumed to be present in the streams with bedrock substrates are provided in table 3.5.3-11. Construction of the Pipeline through bedrock at those streams is likely to require blasting and the estimates in table 3.5.3-11 represent numbers of juvenile coho (67 juveniles expected) that would be displaced and or salvaged prior to blasting. The estimates in table 3.5.3-11 are based on no fish being herded out of the work area prior to dewatering (see Fish Salvage Plan). The actual number that would be salvaged is expected to be much less.

TABLE 3.5.3-11

Worst Case Estimates of Juvenile Fry Coho Present or Assumed as Present at Streams with Bedrock Substrates and Juvenile Fry Salvaged Prior to Blasting during Construction of the Pipeline Project within the SONCC ESU

Subbasin and Fifth-Field Watersheds	Dry Open-Cut w/ Juvenil Fry Coho Present	Juvenile Fry Present at Each Crossing a/	Total Juvenile Fry Present b/	Juvenile Fry Salvaged at Each Crossing c/	Total Juvenile Fry Salvaged d/
Upper Rogue Subbasin					
Trail Creek	2	26	51	17	33
Shady Cove-Rogue River	0	N/A	0	N/A	0
Big Butte Creek	2	26	52	17	34
Little Butte Creek	0	N/A	0	N/A	0
TOTAL	**4**		**103**		**67**

a/ Juvenile Fry Present at Each Crossing based on Juveniles per Mile (see table 3.5.3-6) within a stream crossing length of 145 feet (95 feet construction right-of-way plus an additional 25 feet on each side, a worst case, see text).
b/ Total Juveniles Present (worst case) = number of Juveniles Present at Each Crossing multiplied by number of Dry Open-Cut crossings with potential for blasting and with Juvenile Fry Coho Present.
c/ Juvenile Fry Salvaged at Each Crossing based on Juvenile Fry per Mile (table 3.5.3-6) within a stream crossing length of 95 feet (worst case, see text), not salvaged within the additional 25 feet on each side.
d/ Total Juvenile Fry Salvaged (worst case) = number of Juvenile Fry Salvaged at Each Crossing multiplied by number of Dry Open-Cut crossings with blasting and Juvenile Fry Coho Present. The estimate is based on no fish being herded out of the work area prior to dewatering (see Fish Salvage Plan). The actual number that would be salvaged is expected to be much less.

Underwater Noise

Impulsive type sounds, sound generated by pile driving for example, create stress waves in the piling material that radiate sound throughout the surrounding media of substrate, air, and water and may propagate outward from the source through bottom sediment (Popper and Hastings 2009). Various studies have reported fish mortality, physical injury, auditory tissue damage, decreased viability of eggs, and decreased larval growth due to noise, mostly explosive blasts, seismic survey blasts, and air gun blasts (Hastings and Popper 2005).

State agencies in Washington, Oregon, and California, along with federal agencies have developed interim noise exposure threshold criteria for pile driving effects on fish (WSDOT 2011a; Popper et al. 2006).[3] The threshold noise levels are assumed to be applicable to noise from a mounted impact hammer operating on bedrock substrates for 13 waterbodies potentially affected by the Pipeline project in the Upper Rogue Subbasin (see table 3.5.3-3 and table 3.5.3-10).

Average maximum noise produced by mounted impact hammers due to impact on substrates (e.g., rock) has been reported at 90 dBA from 50 feet away in the air (see Table 7-4 in WSDOT 2011a).[4] Using a simplified conversion of dB between air and water (see footnote, below and Pacific Marine Environmental Laboratory 2012), the noise produced by the impact hammer in air would be equivalent to about 182 dB re: 1 µPa @ 1 meter in water. However, there is no information available to determine whether that noise level would be equivalent to peak sound levels or root mean square (RMS) levels, which are the basis for evaluating potential harm to fish, particularly related to cumulative sound exposure levels caused by multiple impact hammer strikes. However, using the most conservative criteria (cumulative levels which assume multiple impacts over a short period), an impact hammer value of 182 dB is at the limit of the current criteria considered to cause harm (i.e., 183 dB – see Noise section above).

Further, the estimate of noise produced by in-water use of an impact hammer in any waterbody would be influenced by water currents, water depth, and bottom material and topography, as well as configuration and materials of the river banks. The effects of these factors are unknown (WSDOT 2011a). However, noise propagation in any waterbody, upstream and downstream from the construction site would be limited by the stream channels' sinuosity since the propagation is limited to straight-line distance from the source (WSDOT 2011a). Noise produced by impact hammers would be much reduced if construction does not occur within the water column, similar to reduction set back distances from the blast trench to the fish habitat to reduce blast overpressures to below 2.7 psi, discussed above.

Sounds produced by a mounted impact hammer operating in dry conditions might be conducted through bedrock substrate to approach the hearing threshold of fish, as for example the Atlantic salmon, which is around 90 dB re: 1 µPa (see Figure 3 in Hastings and Popper 2005). It is assumed that salmonids in the Pipeline project area at the time of construction would have hearing thresholds similar to Atlantic salmon. With that assumption, listed and non-listed salmonids present at the time of construction might

[3] Interim noise exposure threshold criteria for pile driving effects on fish (Washington State Department of Transportation 2011a) include 1) a cumulative sound exposure level (SEL_{cum}) of 187 dB re 1 µPa² ● s for fishes more than 2 grams, 2) a SEL_{cum} of 183 dB re 1 µPa² ● s for fishes less than 2 grams, and 3) a single-strike peak level (SPL_{peak}) of 206 dB re 1 µPa for all sizes of fishes (WSDOT 2011a).

SEL_{cum} is the cumulative sound pressure squared, integrated over time, and normalized to one second. SEL_{cum} is calculated as SEL (single strike at 10 meters from the pile) + 10 Log(number of strikes).

[4] For consistency, the maximum noise level (L_{max} of the impact hammer at 1 meter (3.28 feet) is computed as:

$$L_{max} = \text{Construction } L_{max} \text{ at 50 feet} - 25 \text{ Log}(D/D_o) = 119.58 \text{ dBA at 1 meter (3.28 feet)}.$$

Where Construction L_{max} = 90 dBA, D = distance from the noise source (3.28 feet) and D_o = the reference measurement distance (here, 50 feet). Noise measured on the A-weighted decibel scale is based on the reference pressure of 20 micro-Pascal (µPa), where one Pascal is the pressure (force of 1 newton) exerted over an area of 1 square meter and applies to sound in the air. Sound in water is referenced (abbreviated as "re:" in reference expressions) to 1 µPa instead of 20 µPa referenced in air.

The characteristic impedance of sound in water (related to the density of water and speed of sound) is approximately 3,600 times the impedance in air, so conversion for the intensity of sounds of equal pressures in air compared to water is 10 Log(3,600) = 36 dB (Pacific Marine Environmental Laboratory 2012). Taking into account the different reference pressures for sound in air and in water (20 µPa and 1 µPa), the intensity measurements for sound of equal pressures differ by 26 dB + 36 dB = 62 dB (Pacific Marine Environmental Laboratory 2012). Using this simplified conversion of dB between air and water, the noise produced by the impact hammer in air (120 dB re: 20 µPa @ 1 m) would be equivalent to about 120 dB + 62 dB = 182 dB re: 1 µPa @ 1 m in water.

detect the noise produced by an impact-hammer striking bedrock, but the noise is not expected to be of sufficient intensity to cause them injury as would SELs produced by pile driving.

Dry open-cut construction, more than likely dam-and-pump methodology, would be used at sites where blasting and/or mounted impact hammers would be required to construct a trench through bedrock substrates. When using the dam-and-pump stream crossing methodology, the typical right-of-way distribution of an isolated streambed (dry open-cut) would be no less than 25 feet on one side of the pipe trench and at least 50 feet or more on the opposite side of the pipe trench depending on whether it is a 75- or 95-foot-width crossing. Therefore, an area within the waterbody crossing equivalent to length of the blasting trench and approximately 25 feet wide (in the worst-case scenario) would be exposed to instantaneous hydrostatic pressure changes above 2.7 psi. In reality, the distance in water affected outside of the 25 feet on land would be less than an additional 25 feet because water does not transmit energy pressure waves as well as rock (only about 70 percent of the distance away from the charge relative to rock, the most conductive substrate of pressure waves; see calculations in ADFG 1991, which the maximum distance is based upon. As noted above (see the Acoustic Shock subsection), a *Fish Salvage Plan* is in place that would result in any fish present being removed from the area within this 25-foot potential effect area, eliminating potential noise effects from stream crossings.

There would be no in-water blasting, and no in-water noise monitoring has been proposed. Procedures for conducting blasting in-the-dry have been provided in the *Blasting Plan* (appendix C to the POD). Monitoring for efficacy of each stream crossing and fish salvage would be conducted throughout the entire process, including function of upstream block nets to exclude fish from areas where they might be affected by blasting in the dry, thus eliminating potential noise effects to fish during stream crossings. In situations where blasting occurs in uplands adjacent to streams or within dry streambeds, PCGP would attempt to minimize shock waves from blasting that may affect aquatic resources by optimizing variables such as the types of explosives selected, the size of charges, and the sequences of firing. In-air noise due to blasting would be mitigated in all noise-sensitive areas as described in PCGP's *Blasting Plan* (see appendix C to the POD).

Suspended Sediment by Pipeline Crossing Methods

The three crossing methods that would be used for crossings where SONCC coho salmon may occur include dry crossing, conventional direct bore, and HDD. Dry crossing methods including diverted open cut would result in minimal impacts, including temporary increases in suspended sediments in restricted areas. Bores and HDDs would be installed without in-water work and would not directly affect the aquatic environment and associated species, except in the case of an inadvertent return during an HDD crossing, which could affect stream suspended sediment levels as discussed below.

Suspended Sediment – Dry Open-Cut

Pipeline crossings of surface waterbodies would cause some downstream turbidity and sedimentation. The type of crossing and stream sediment characteristics can affect turbidity and suspended sediment in streams. All streams in the range of SONCC coho salmon ESU would be crossed using the dry open-cut method (flume and dam-and-pump) (table 3.5.3-3 and table 3.5.3-10), except for two waterbodies crossed by HDD and bore. Within the range of the SONCC ESU, the Rogue River would be crossed with an HDD, while the Medford Aqueduct would be crossed by a bore. Turbidity and sedimentation impacts from the dry open-cut methods are associated with: 1) installation and removal of the upstream and downstream dams used to isolate the construction area; 2) water leaking through the upstream dam and collecting sediments as it flows across the work area and continues through the downstream dam; 3) movement of in-stream rocks and boulders to allow proper alignment and installation of the flume and dams; and 4) when streamflow is returned to the construction work area after the crossing is complete and the dams and flume are removed. Both "dry" techniques produce much less sediment in the water than alternative "wet" open cut methods (Reid and Anderson 1999; Reid et al. 2002; Reid et al. 2004, Reid et al. 2008, Harper 2012). Therefore, if properly installed and maintained during construction and restoration, dry open-cut construction across waterbodies would produce minor levels of sediment and turbidity.

PCGP would minimize impacts on surface waters and aquatic resources by implementing the waterbody crossing and erosion and sediment control measures as described in the Pipeline project-specific ECRP. Actions described in GeoEngineers (2017d) would also be used to determine level of stream crossing risk. GeoEngineers, using a combination of field data and GIS data, rated proposed stream crossings based on the matrix along the entire route, including 20 streams in the range of SONCC coho. The matrix has two axes rating the crossing based on the Pipeline impact potential at the crossing and the relative stream response potential at the crossing. Each crossing was rated as low, medium, or high for each of the two axes (all stream crossings were placed into one of nine categories, such as Low–Low, Low–Medium, and Medium–High). Crossings of all streams except for Neil Creek were evaluated as having sensitive streambed, banks, or riparian revegetation conditions that would require site-specific measures to maintain channel stability or replace disturbed habitat (GeoEngineers 2017d) at each stream crossing. The crossing of Neil Creek would require typical stream crossing methods to reduce impacts to waterbody crossings. PCGP would stabilize the construction site, including the streambanks, immediately following installation of the Pipeline. PCGP would also install and maintain throughout construction sediment barriers, such as silt fence and straw/hay bales, to prevent sedimentation from surface runoff into a stream.

Construction across waterbodies would be completed as quickly as possible to shorten the duration of sedimentation and turbidity. If channels are dry during construction, small streams (less than 10 feet) are projected to be crossed in less than 24 hours, and intermediate streams (10 to 100 feet) usually in less than 48 hours. Times may be longer when flow diversion is required. Reid et al. (2004) noted that in flowing streams they monitored, in-stream work averaged 38 and 64 hours for dam-and-pump and flumed crossings, respectively. If circumstances required a construction delay, adequate site stabilization measures would be employed in accordance with the ECRP and permit conditions. However, failure of flow sealing and other in-stream structures at upstream diversions structures can occur from a variety of malfunctions such as pump failure, dam and flume failure, poor dam seal and others. Reid et al. (2004) noted seal failures of monitored diverted open cut crossing in one of 23 dam-and-pump projects and five of 12 for flumed projects. Should these occur, suspended sediment would be relatively elevated over those without failure, but immediate repair work could reduce the magnitude and duration of elevated suspended sediment.

Alternatively, Harper (2012) modeled sediment entrained during wet open-cut pipeline crossings of six major (width >100 feet), 46 intermediate (widths >10 feet and <100 feet), and 227 minor waterbodies (widths <10 feet) in New Hampshire. In-stream duration of suspended sediment generation varied by major waterbody (30 hours), intermediate waterbody (12 hours), and minor waterbody (8 hours). In addition, modeling included suspended sediment generated following dry open-cut crossing of intermediate and minor waterbodies but was restricted to a one hour period of duration associated with a "quick-flush" that occurs after a pipe is installed, the trench is backfilled, and water barriers, upstream and downstream from the workspace, are removed and turbulent, high energy flow across the backfilled trench suspends sediments which are expected to last for one hour (Harper 2012). The effect on suspended sediment from planned dry crossings and unintended wet cuts crossings with repairs are discussed below in this subsection.

Severity of Effects from Suspended Sediment

Salmonids exposed to moderate to high levels of suspended sediment for extended periods could be adversely affected. At high levels, turbidity directly affects survival and growth of salmonids and other species, interferes with gill function, and adversely affects substrate for egg development (reviewed and compiled by Bash et al. 2001). Turbidity can also reduce macrophyte cover (over the long-term) by limiting photosynthesis (Goldsborough and Kemp 1988), as well as adversely affecting fish vision, which is a requisite for social interactions (Berg and Northcote 1985), feeding (Vogel and Beauchamp 1999; Gregory and Northcote 1993), and predator avoidance (Meager et al. 2006; Miner and Stein 1996).

Salmonids may avoid areas of increased turbidity levels at 20 mg/l suspended sediment, and possibly lower concentrations depending on length of exposure (Newcombe and Jensen 1996). The elevated suspended sediment conditions would be short-term during pipeline installation and would not be continuous at any one location. This would reduce the chances of continuous elevated exposure for fish that are relatively sedentary. . Some other studies have found varied effects including lesser effects at these concentrations, with overall effects related to both duration as well as concentration (Newcomb and Jensen 1996).

Sediment stirred into the water column can be redeposited on downstream substrates, which could bury aquatic macroinvertebrates (an important food source for salmonids, and other fish in estuarine areas). Additionally, downstream fine particle sedimentation could affect spawning substrate habitat, spawning activities, eggs, larvae, and juvenile fish survival, as well as benthic community diversity and health (reviewed and compiled by Bash et al. 2001). Because the effects of increased sedimentation and turbidity are often limited to the period of in-stream work, the duration of these effects are usually relatively short. However, specific site characteristics including flow, substrate composition, relative disturbance and other factors could make the duration of construction effects last longer. One long-term study (during construction through three years after construction) of multiple pipeline crossings of coldwater streams found no measurable effect to fish or benthic resources or their habitat within 2 months to 3 years of construction (Blais and Simpson 1997) and Gartman (1984) reported rapid recolonization of benthic organisms on 30 pipeline projects post-construction.

Dry open-cut construction methods have the potential to alter fish abundance over the short-term. Reid et al. (2002) found that fish abundance downstream of dam-and-pump or flumed crossings reduced immediately after construction in two of four sampled sites. Mean sediment concentrations during construction at these four sites were all less than 100 mg/l (range 8 to 86 mg/l). Two sites sampled one month later had downstream reductions in fish abundance including brook trout. However, Reid et al. (2002) concluded, based on limited physical sediment-related stream changes, observed differences in fish abundance for most sampling were likely the result of factors other than project-generated sediment, such as low flow generated from water diversion actions and fish sampling methodsOne year after construction, Reid et al. (2002) found no difference in fish abundance below these two sites from preconstruction levels.

Newcombe and Jensen (1996) compiled research from many sources that demonstrate effects to anadromous and resident salmonids by various levels of suspended sediment and exposure over time. This modelling process is used to assess the possible effects to salmonid resources in the project area from in-stream pipeline construction based on estimates of TSS concentration and exposure duration.

The developed models that approximate the level of effect are based on known levels of suspended sediment concentration and duration of exposure to that concentration in a stream. In order to use these models to estimate effects to salmonids, an estimate of these two parameters is needed.

Output from each model provides severity-of-ill-effects (SEV) scores that are summarized below. Values range from 0 to 14, where an SEV of 0 indicates no effects, an SEV between 1 and 3 indicates behavioral effects, an SEV from 4 to 8 indicates sublethal effects, and an SEV from 9 through 14 indicates lethal and paralethal effects (see Table 1 in Newcombe and Jensen 1996).

<u>Behavioral Effects SEV scores</u>

1 = Alarm reaction
2 = Abandonment of cover
3 = Avoidance response

<u>Sublethal Effects SEV scores</u>

4 = Short-term reduction in feeding rates and/or feeding success
5 = Minor physiological stress (increase coughing rate and/or increased respiration rate)
6 = Moderate physiological stress
7 = Moderate habitat degradation; impact on homing
8 = Major physiological stress; long-term reduction in feeding rate- feeding success; poor condition

<u>Lethal and Paralethal Effects SEV scores</u>

9 = Reduced growth rate, delayed hatching, and/or reduced fish density
10 = 0 to 20 percent mortality, increased predation, and/or moderate to severe habitat degradation
11= >20 to 40 percent mortality
12= >40 to 60 percent mortality
13= >60 to 80 percent mortality
14= >80 to 100 percent mortality

SEV scores are complex interactions of TSS concentrations and time of exposure to those concentrations where higher concentrations and longer exposures result in higher SEV scores and greater impact to fish. Effects of high concentrations may be ameliorated by brief exposures and conversely effects of low concentrations may be exasperated by prolonged exposures. In the analyses, downstream effects of TSS are primarily caused by very fine sand, silt and clay particles; coarser sediments settle out of suspension over relatively short distances downstream, closer to the crossing site. Specific information about each waterbody crossing is required to predict amounts of suspended sediment that would be generated, transported, and deposited downstream. That information includes: 1) stream width and depth, 2) water velocity, 3) streambed roughness, 4) grain size of excavated materials, and 5) background (ambient) levels of suspended sediment (Reid et al. 2008). Once total suspended sediment (TSS) concentrations generated by in-stream activities have determined, they are applied in the dose-response assessments of sediment exposure, the SEV models by Newcombe and Jensen (1996).

<u>Estimates of Likely Effects from Suspended Sediment</u>

<u>Average Channel Characteristics.</u> PCGP incorporated site data, regional data, and available literature based models to provide an estimate of both suspended sediment levels and extent of effects to SONCC coho salmon ESU from construction across streams. Specific channel characteristics for streams crossed by the Pipeline are not available. However, data provided in the ODFW (2014c) stream

surveys included bankfull channel widths, bankfull depths, and stream gradients, in addition to substrates (Sand-Silt-Organics) noted in table 3.5.3-8 above, for multiple streams within fifth-field watersheds crossed by the Pipeline (see table 3.5.3-12). Those data were used to develop stream channel characteristics in each fifth-field watershed crossed that are assumed to apply to the actual streams that would be crossed in each of the watersheds.

TABLE 3.5.3-12

Channel Conditions for Streams Sampled during the Aquatic Habitat Inventory (ODFW 2014c) in Four Watersheds within the SONCC ESU that would be Crossed by Pipeline Project

Subbasin and Fifth-Field Watersheds	Number of Stream Reaches Surveyed a/	Average Values for Streams Sampled in Watershed a/			
		W = Bankfull Width (meters)	D = Bankfull Channel Depth (meters)	S = Channel Gradient (percent slope)	Percent Sand, Silt, Organics in Substrate

Little Butte Creek	56	9.11	0.58	5.37	30.36

a/ Stream-specific values are provided in appendix Y.

Estimates of Bankfull Flows. Sediment transport in streams depends, in part, on stream channel characteristics. Stream-specific values that were averaged in table 3.5.3-11 were used to determine stream discharged rate (Q) and water velocity (V_A). Manning's Formula (Limerinos 1970; Arcement and Schneider 1989) was used to estimate Q, the stream discharge rate (cubic meters per second):

$$Q = A\ (k/n)\ (R^{2/3})\ (S^{1/2})$$

with estimates of A, the cross-sectional area of a stream (square meters); R, the hydraulic radius (meters, where R = A/P, and P is the wetted perimeter in meters); S, the slope of channel (channel gradient); the constant *k* equals 1.486 if English units are used or 1 with metric units; and n, Manning's roughness coefficient. Stream-specific Aquatic Habitat Inventory data (see sppendix Y) were used to estimate the stream channel cross-section shape and cross-section area. If the predominant depth was greater than half the bankfull width, the cross-section channel shape was assumed to be a V. If the bankfull depth was less than half the bankfull width, the cross-section channel shape was assumed to be a trapezoid with each bank as a 1:1 slope, dependent on predominant depth (bottom = W – 2 D). If the bankfull depth was equal or greater than half the bankfull width, the cross-section channel shape was assumed to be a V. Manning's n was estimated from various sources (Chow 1959; Limerinos 1970; Arcement and Schneider 1989) and ranged from n = 0.060 for floodplain channels with light brush and trees in summer, to n = 0.050 for channels with pools, shoals and stones, to n = 0.045 for mountain streams with bottom gravels, cobbles, and boulders and no vegetation in the channel (Chow 1959).

Estimates of Q derived with Manning's Formula are assumed to be measures of the carrying capacity (bankfull flow) of a particular channel section (Arcement and Schneider 1989). Carrying capacity of a channel section is assumed to occur during periods of high flow, generally during winter months in the project area. Stream flow rate or discharge rate, Q, is related to cross-sectional area (A) and average streamflow velocity (V_A):

$$Q = A \cdot V_A\text{, alternatively } V_A = Q / A$$

Estimates of variables used to derive Q and V_A are provided in table 3.5.3-13, averaged by watershed.

TABLE 3.5.3-13

Estimates Used to Derive Bankfull Flow and Bankfull Velocity in Four Watersheds within the SONCC ESU that would be Crossed by Pipeline Project

Subbasin and Fifth-Field Watersheds	Average Estimates for Streams Sampled in Watershed a/				
	A = Channel Cross Sectional Area (meter^2)	P = Wetted Perimeter (meters)	R = Hydraulic Radius (meters)	Q = Bankfull Flow (meter^3/sec)	V_A = Bankfull Velocity (meter/sec)
Upper Rogue Subbasin					
Trail Creek	5.40	8.54	0.59	19.10	3.79
Shady Cove-Rogue River	9.65	12.43	0.65	31.06	3.24
Big Butte Creek	4.74	9.17	0.48	11.01	2.45
Little Butte Creek	5.68	9.58	0.50	15.87	2.86

a/ Stream-specific estimates are provided in appendix Y.

Seasonal Discharge. Pipeline construction across waterbodies would occur during ODFW (2008) in-stream construction windows (see section Timing to Life History Functions, above). Hydrographs of monthly discharges of waterbodies within the Upper Rogue Subbasin to be crossed by the Pipeline (see figure 3.5.3-5) show peak seasonal flows during winter months, December through February. Lowest flows occur during summer months, coinciding with the ODFW construction windows. Assuming that high winter stream flows correspond to the bankfull carrying capacities of channel sections (Arcement and Schneider 1989), in-stream flows during the ODFW construction window would be some fraction of the winter flows. Those fractions are included in table 3.5.3-14 with the mid-point which is used to adjust bankfull flows and velocities to low flows and velocities for each of the sampled reaches in the ODFW Aquatic Habitat Inventory data (see appendix Y).

TABLE 3.5.3-14

Recorded High Flows During Winter and Average Low Flows During the ODFW In-stream Construction Window in Hydrographic Data within the Upper Rogue Subbasin Crossed by the Pipeline Project

Hydrograph	High Flow (cfs) (Month)	In-stream Construction Window	Average Low Flows (cfs) During Window	Percent of High Flow During Window	Percent Mid-Point
Big Butte Creek	372 (Jan)	Jun 15- Sep 15	62.1	16.7	9.65
Elk Creek	537 (Jan)	Jun 15- Sep 15	13.7	2.6	

The 10-year average of low water stream flows in the Upper Rogue Subbasin during the ODFW in-stream construction window are assumed to be 9.65 percent of high winter flows (see table 3.5.3-15), based on discharge data for Big Butte Creek and Elk Creek during December (see figure 3.5.3-5). Stream depths for all waterbodies within the Upper Rogue Subbasin were reduced by the same proportion through iterations that reduced bankfull flows by 9.7 percent in all streams in the Aquatic Habitat Inventory samples. Reduced stream depths generate reduced values of A, P, and R in Manning's Formula. Stream-specific estimates of Q and V_A during low water flow conditions were likewise derived and are provided in table 3.5.3-15, averaged by watershed. Reduced stream depths generated reduced values of A, P, and R in Manning's Formula.

Background Turbidity and Suspended Sediment. Turbidity, generally reported in NTUs, is a measure of the lack of transparency (cloudiness) of water caused by suspended or dissolved substances that cause light to be scattered and adsorbed. Turbidity is often measured on-site using a turbidity meter that measures the scattering of light in a water sample relative to a known range of turbidity standards. Turbidity is directly related to the concentration of sediments suspended in water, but the relationship between turbidity and suspended sediment is complicated by sediment particle size, particle composition, and water color (ODEQ 2010).

GeoEngineers (2017f) evaluated the potential risk of turbidity increasing during construction of the Pipeline across waterbodies. The qualitative evaluation was based on each affected waterbody's hydroperiod, presence of erodible clay and loam soils in streambanks, presence of clay in streambed (suspended clay contributes to turbidity disproportionally to its erodibility), long-term stability of stream channels, and level/duration of construction effort and stabilization measures likely added at the time of construction. The turbidity risk was scored from 1 (low) to 5 (high). Of 86 waterbodies evaluated within range of SONCC coho, 58 were scored with a low risk (score of 1 or 2) of turbidity increase over a 24-hour period, and 27 were scored with a moderate risk (score of 3 or 4), generally due to soil erosion potential, presence of clay or mud, and/or the presence of steep slope or an incised channel that would require construction of a deep trench (GeoEngineers 2017f). The evaluation concluded that turbidity generated during construction may exceed Oregon water quality standards for short distances and short durations downstream from each stream crossing, either coinciding with construction across perennial waterbodies or in intermittent streams coincidental with autumn precipitation.

Ambient turbidity was not addressed by GeoEngineers (2017f). Turbidity (NTU) has been evaluated by ODEQ (2013) and retrieved from Laboratory Analytical Storage and Retrieval (LASAR) Web Application in 2013 before ODEQ discontinued support of the site (ODEQ 2017), making the data unavailable. Turbidity within individual streams may be highly variable, but during the period coinciding with ODFW (2008) in-stream construction windows, reported turbidity was minimal and of low variability in streams for which data exists (see table 3.5.3-16).

The majority of ODEQ LASAR data were turbidity measurements (in NTU) taken in the field. TSS values were occasionally reported but mostly without measuring the corresponding turbidity. Relationships between turbidity and suspended solid concentrations are best if determined on a stream-by-stream basis (Downing 2008). However, since stream-specific data for turbidity and TSS were not available, four available literature-generated models were used to supply a reasonable range of the possible relationships. Relationships are reported for streams in Alaska (Lloyd 1987; Lloyd et al. 1987) and streams in the Puget Lowlands (Packman et al. 1999); the models are non-linear. At low turbidity levels (see table 3.5.3-16), conversions of NTUs to TSS are relatively consistent among the models. Based on these conversions, an overall background level of 2 mg/l is assumed for TSS concentrations for all streams crossed by the Pipeline during the ODFW in-stream construction window. Turbidity data (NTU) from the stations included in the table averaged for July, August, and September yielded an average of 1.3 NTUs. When converted to TSS using the models in the table, the conversion yields an average of 1.9 mg/l as a background level within range of the SONCC coho. In support of that assumption, ODEQ (2010) reported that during dry seasons, background turbidity levels are relatively low and consistent in small streams throughout Oregon. A background TSS concentration of 2 mg/l during summer is also consistent with measurements reported by USGS in Myrtle Creek, Big Butte Creek, and the Rogue River mainstem during summers 1977, 1978, and 1979 (historical data provided by the Forest Service). Results from the ODEQ data analysis and other sources reported above support using 2 mg/l as ambient TSS levels during the in-stream crossing period including all or portions of July, August, and September.

a/ Models used to convert Turbidity (T) to Suspended Solids Concentration (SSC) or Total Suspended Solids (TSS) in waterbodies crossed or proximate to the Pipeline project. Turbidity information source: ODEQ (2013) included data collected prior to 2013.
Model 1 (Lloyd 1987; Lloyd et al. 1987) applicable to waters throughout Alaska: $T = 0.44\ (SSC)^{0.858}$
Model 2 (Lloyd 1987; Lloyd et al. 1987) applicable to interior Alaskan streams: $T = 1.103\ (SSC)^{0.968}$
Model 3 (Packman et al. 1999) Rutherford Creek, King County, Washington: $\ln(TSS) = 1.32 \ln(NTU) - 0.68$
Model 4 (Packman et al. 1999) nine streams sampled in the Puget Lowlands, Washington: $\ln(TSS) = 1.32 \ln(NTU) + 0.15$

NTU – nephelometric turbidity unit

Particle Transport. Sediment particles would be transported distances downstream (L, in meters) based on 1) the particle size and settling velocity (V_S, - centimeters per second – in water at 20°C, see for example the Wentworth Grain Size Chart, USGS 2003), 2) the average streamflow velocity (V_A - meters per second), and 3) the average depth of flow (D, meters) downstream, using the following "velocity-distance-time" equation;

$$L = V_A\ (D / V_S)$$

Estimates of transport distances (L, meters) for various sediment particles ranging in sizes from clay to coarse gravel are provided, as examples, in table 3.5.3-17 for three waterbodies in the Pipeline project vicinity for which data are available. Particle sizes deleterious to salmonids (250 µm or less in the models of Newcombe and Jensen 1996, above) could settle out of suspension less than 1 meter (0.2 feet) downstream (e.g., medium sand in low flows for Tributary to Catching Creek). Alternatively, particles could remain suspended for 4.7 kilometers (2.9 miles) or more (very fine silt in Willis Creek).

TABLE 3.5.3-17

Estimated Downstream Transport Distances for Particles (ranging from Very Fine Silt to Coarse Gravel) in Three Streams (as examples).

Particle Description	Particle Diameter a/	Settling Velocity (V_S)	Estimated Particle Transport Distance (L) Downstream b/		
			Tributary to Catching Creek	Steele Creek	Willis Creek
Coarse Gravel	1.60 cm	90 cm/s	0 m	0 m	0 m
Very Coarse Sand	0.1 cm	15 cm/s	0 m	0 m	0 m
Coarse Sand	0.05 cm	8 cm/s	0 m	0 m	1 m
Medium Sand	0.025 cm	3 cm/s	0 m	0 m	2 m
Fine Sand	0.0125 cm	1.25 cm/s	0 m	1 m	5 m
Very Fine Sand	0.0062 cm	0.329 cm/s	1 m	4 m	20 m
Coarse Silt	0.0031 cm	0.085 cm/s	3 m	16 m	78 m
Medium Silt	0.0016 cm	0.023 cm/s	9 m	59 m	289 m
Very Fine Silt-Clay	0.0004 cm	0.0014 cm/s	153 m	977 m	4,742 m

a/ note that 0.025 cm = 250 µm

b/ Parameter values used to estimate L:

Trib. Catching Creek: V_A =0.27 m/s; D = 0.01 m.
Steele Creek: V_A = 0.53 m/s; D = 0.03 m.
Willis Creek: V_A = 0.66 m/s; D = 0.1 m.

Sediment Generated During Pipeline Construction. Modeled concentrations of TSS produced in waterbodies during wet open-cut pipeline construction were developed from empirical data collected during construction across 15 to 19 streams in North America (Reid et al. 2004). Models were developed to predict mean TSS concentrations immediately downstream (approximately 50 meters) of pipeline construction sites. Models included TSS generated by all construction activities and by trenching, pipe lowering, and backfilling. The models predicting mean TSS generated by all activities (including trenching, pipe lowering, and backfilling) had the highest correlation coefficients (Reid et al. 2004). The model predicting mean TSS ($\boldsymbol{C}_{\mathbf{av}}$) at about 50 meters downstream by all activities associated with wet open-cut pipeline construction is:

$$C_{av} = 1.5 \text{ x } 10^6\ U^{1.09}\ d_{50}^{0.95}\ P_f^{0.35}\ q^{-1}$$

where U = mean flow velocity (m per second) at the crossing location during the construction period, equivalent to V_A derived using Manning's Formula (table 3.5.3-14 and appendix Y); d_{50} = the median sediment size (m) of the excavated material by weight, P_f = percentage of fines (silt and clay) in the excavated material (%) and is assumed to equal the percent of silt and organics in surface substrates for all streams within a given fifth-field watershed (estimated as 2/3 of the Percent Sand, Silt, Organics in Substrate tabulated in table 3.5.3-12); q = the width adjusted stream flow rate where $q = Q/B$, (m^2 per second) with B = the watercourse width (m) adjusted for a particular flow rate and Q = stream flow rate (m^3 per second) derived using Manning's Formula (values for Q are in table 3.5.3-15 and appendix Y). Values for d_{50} in these analyses were derived by regressing values of d_{50} and P_f provided in Table 2 of Reid et al. (2004); the relationship of d_{50} to P_f from that study is d_{50} = 38.12 e $^{-0.0963\ Pf}$ (r^2 = 0.636, P<0.001).

In these simulations, Q is related to B through Manning's Formula and as B increases numerically, Q also increases but at a faster numerical rate (as a power function). If all other model parameters are held constant in the Reid et al. (2004) model, increased width adjusted stream flow rate, q (due high flow, Q, and proportionally smaller watercourse widths, B) would decrease the TSS concentration (C_{av}) because *q* is factored as q^{-1} in the equation. Conversely, lower *q* values would generate higher C_{av} with all other parameters in the equation held constant. Stream-specific estimates of U, d_{50}, P_f, q^{-1}, and C_{av} during low water flow conditions are provided in appendix Y and averaged by watershed in table 3.5.3-18.

a/ Stream-specific values are provided in appendix Y.

In addition to developing predictive models of TSS concentrations generated by wet-open cut pipeline construction, Reid et al. (2004) measured TSS downstream from 12 flumed pipeline crossings and 23 dam-and-pump crossings (dry open-cut or isolated pipeline construction crossings) with comparisons to 11 wet open-cut construction crossings. By accounting for flow, background TSS concentrations, sampling distance downstream, and duration of construction, Reid et al. (2004) determined that mean TSS concentrations generated during dry open-cut construction by fluming were 3.7% of the wet open-cut concentrations and were 0.85% of the wet open-cut concentrations for dam-and-pump construction. These relationships were used in table 3.5.3-19 to adjust average TSS concentrations estimated at 50 meters downstream from wet open-cut pipeline crossings to average TSS concentrations at flumed pipeline crossings and dam-and-pump pipeline crossings.

<u>Estimated Downstream Concentration of Suspended Sediments</u>. Ritter (1984) provided a variant of the "velocity-distance-time" equation, above to estimate concentrations of suspended sediments (C_X, as mg/L) some distance (x) downstream from a pipeline trench being constructed across a waterbody. Ritter's model for downstream sediment transport distance during construction across minor streams, with complete mixing of sediment particles, estimates the concentration downstream C_X by:

$$C_X = C_O\, e^{-(vs/d)(x/u)}$$

where C_O (mg/L) is the initial concentration of suspended solids in the water column at the trenching site, vs = the settling velocity (m/second) of sediment particles, d = stream depth (m), and u = stream current velocity (m/second).

The formula for estimating the concentration downstream (Ritter 1984) is used to estimate the distance downstream for TSS concentrations at 50 m (C_O) to equal assumed ambient concentrations (C_X = 2 mg/l). The estimate is calculated by solving for x (distance) in the equation with appropriate transformations and inclusion of only the estimated clay fraction as TSS concentration since the silt fraction would have settled out of suspension:

$$x = (\ln(C_X) - \ln(C_O)) + (d / vs)\, u$$

where x = distance (m) downstream, C_O = the initial concentration (mg/l) of suspended solids in the water column at the trenching site, vs = the settling velocity (m/second) of the clay fraction, d = stream depth (m), u = stream current velocity (m/second), and x = distance (m) downstream. The distances x for TSS generated by wet open-cut construction techniques to attenuate to ambient TSS (C_X) is provided in table 3.5.3-19.

TABLE 3.5.3-19

Inverse relationships between TSS concentrations produced at 50 meters from in-stream construction and TSS concentrations at variable distances downstream were evaluated for each of the three pipeline crossing techniques by nonlinear regressions of distance downstream (from 1 to 1000 m) and total TSS concentrations at distance x, solving for x in the above equation [$x = (\ln(C_X) - \ln(C_O)) + (d / vs) u$]. Best fit regressions were selected (exponential vs. logarithmic) to model the inverse relationships between distance and TSS concentration for data averaged in each watershed. Those regression equations provided in table 3.5.3-20 define the nonlinear relationships between y = concentration (mg/l) and x = downstream distance (m).

TABLE 3.5.3-20

Nonlinear Regression Equations (with Coefficients of Determination, r^2) for Estimating TSS Concentrations (y, mg/l) at Distances Downstream (x, m) during In-stream Construction in Four Watersheds within the SONCC ESU to Be Crossed by the Pipeline Project

Little Butte Creek	$y = 742.68\ e^{-0.0007x}$ $r^2 = 0.958$	$y = 27.64\ e^{-0.0007x}$ $r^2 = 0.958$	$y = 6.33\ e^{-0.0007x}$ $r^2 = 0.958$

Suspended Sediment Downstream Effects. Newcombe and Jensen (1996) developed six different models assessing effects of TSS on various fish and habitat groupings. As noted above, the model addressing effects on both adult and juvenile stages of salmonids (Model 1) provides the best overall assessment of general level of severity of effects for juvenile and adult coho salmon in project area streams at the time of instream construction. Input for the model includes TSS concentration (mg/l) and duration (hours) of exposure to the suspended sediments and has the form:

$$z = a + b\,(\log_e x) + c\,(\log_e y)$$

where z = SEV score, x = duration of exposure in hours, and y = concentration of suspended sediment in mg/l. Constants a, b, and c were empirically derived for Model 1, used here, and other models (see Table 3, in Newcombe and Jensen 1996). If duration of exposure is known, and z (SEV) is set as a defined value, TSS concentration for that defined SEV score can be computed as:

$$y = e^{((z - a) - b\,(\log e\ x))\,/\,c} \text{ or } y = \exp\,(((z - a) - (b\,(\log_e x)))\,/\,c$$

In any of the Newcombe and Jensen models, there is a nearly consistent range for the whole number z, varying from z – 0.5 to z + 0.49. For example, if SEV = 3, the range for that score in the exponential equation, above would be between 2.50 and 3.49; for SEV = 5, the range is 4.5 to 5.49, and so on. For any given duration of exposure (x), the TSS concentration (y) is minimized using (z – 0.5) in the solution. Using the minimum TSS concentration for any given SEV score maximizes the predicted downstream distances for that concentration when solving the regression equations in table 3.5.3-20 for each of the three waterbody crossing methods in each of the four watersheds.

Duration of Exposure. Following recommendations by NMFS (2017i), personnel with pipeline contractor EnSite USA were asked to provide typical durations, based on their experience, for in-stream time requirements for placing and removing isolation structures for streams in different width categories. High pulses of sediment suspended during dry open-cut procedures are generated during installation and removal of isolation structures prior to and after fluming or dam-and-pump installation, trenching, pipe installation, and trench backfilling. EnSite provided the following durations of typical sediment pulses for four stream width classes during installation of stream-crossing structures: for widths ≤10 feet, 2 hours; widths >10 feet to ≤25 feet, 4 hours; >25 feet to ≤50 feet, 5 hours; and >50 feet to ≤100 feet, 6 hours. EnSite also provided the following durations of sediment pulses for the same four width classes during removal of dry open-cut crossing structures: for widths ≤10 feet, 2 hours; widths >10 feet to ≤25 feet, 3 hours; >25 feet to ≤50 feet, 4 hours; and > 50 feet to ≤100 feet, 5 hours. Numbers of streams in range of SONCC coho and streams with assumed coho presence within those four width categories that would be crossed by the Pipeline in each watershed are provided in table 3.5.3-21 using the worst case of structure installation. In general, there are very few streams with widths >25 feet.

TABLE 3.5.3-21

SEV Scores Downstream. Durations for in-stream sediment generating actions provided by EnSite USA from table 3.5.3-21 are used in table 3.5.3-22 with minimumTSS concentrations for specific SEV scores ranging from minor behavioral effects (SEV = 1, alarm reaction) to extreme sublethal effects (SEV = 8, major physiological stress) to estimate the maximum downstream distances at which those severity of ill effects would occur to SONCC coho by in-stream construction across streams in the four watersheds.

Failures of isolation structures to exclude streamflow during fluming or dam-and-pump would result in suspended sediment entrained downstream, assumed to be equal to TSS levels generated during wet open-cut in table 3.5.3-22. Scenarios of exposures as long as six hours could occur while work crews repair the failed isolation structures. Six-hour exposure would cause SEV = 7 (moderate habitat degradation, impaired homing) for all stream widths but would not cause major physiological stress (SEV = 8) to SONCC coho. Longer exposures could be required if dry open-cut construction (flume or dam- and-pump) is abandoned, and the waterbody crossing is completed using wet open-cut construction.

Values of 0, in columns associated with specific SEV scores and TSS concentrations in table 3.5.3-22, indicate that there are no distances downstream from construction by wet open-cut or dry open-cut (flume or damp-and-pump) that the specified TSS concentration and exposure duration during a particular crossing method would generate the SEV score for that column in that watershed. For example, there is no distance downstream for construction during fluming in the Trail Creek watershed at which a SEV score = 5 if the TSS value is 59.4 mg/l and the exposure duration is 2 hours.

TABLE 3.5.3-22

a/ Durations for wet open-cut indicate time to repair isolation structures after failure. Durations for dry open-cut from table 3.5.3-21.

b/ Maximum downstream distances from solving SEV equation ($Y = e^{((z-a)-b(\log_e x))/c}$) for concentration (Y) by minimizing SEV scores (Z -0.5) and using durations (hours) from table 3.5.3-21. Concentrations derived from appropriate equations, table 3.5.3-20.

The modeling results provided in table 3.5.3-22 reveal the maximum downstream distances that TSS generated by each of the crossing methods would attenuate to the concentrations shown (rows labeled TSS (mg/L) with specific durations based on stream width (groupings labeled with width category and hours) that would yield a specific SEV score (columns SEV=1 to SEV=8) for fluming or dam-and-pump crossing methods. Using estimates for fluming in streams <10 feet wide within the Little Butte Creek watershed as an example, for the range from distance = 0 (actually 50 meters downstream from the trench as applied in the Reid et al. 2004 model for average TSS generated by all activities) to distance = 843 m, SEV =4 with TSS concentration = 15.3 mg/l and duration = 2 hours. Other estimates include:

- From downstream distance = 843 m to distance = 2,778 m, SEV = 3 with TSS concentration = 3.95 mg/l and duration = 2 hours.
- From downstream distance = 2,778 m to distance = 4,712 m, SEV = 2 with TSS concentration = 1.02 mg/l and duration = 2 hours.
- From downstream distance = 4,712 m to distance = 6,647 m, SEV = 1 with TSS concentration = 0.26 mg/l and duration = 2 hours.
- Past distance = 6,647 m downstream, SEV = 0.

Evident from examining table 3.5.3-22, no flumed crossings in any of the four watersheds would yield SEV scores greater than 4 (sublethal effects including short-term reduction in feeding rates and/or short-term reduction in feeding success) for any of the stream crossing width categories. Likewise, no crossings with dam-and-pump procedures applied would cause SEV scores greater than 3 (behavioral effects, specifically avoidance response) for any of the stream crossing width categories. Except for possible failures of isolation structures that would cause TSS concentrations similar to wet open-cut procedures with exposures as long as 6 hours (discussed above), no in-stream construction would cause minor or major physiological stress (SEV scores 5 to 8, respectively; see Newcombe and Jensen 1996) or cause lethal conditions for juvenile and adult salmon. A failure of crossing isolation structures lasting for 6 hours or more would cause an SEV score of 7 or higher for at least 965 m downstream from dry open-cut crossings within three streams with critical habitat crossed in the, in the Trail Creek watershed, for at least 517 for one stream with critical habitat cross in the Shady Cove-Rogue Rive watershed, for 813 m downstream within two streams with critical habiats in the Big Butte Creek watershed, and for 1,030 m downstream within two streams with critical habitats in the Little Butte Creek watershed. To ensure an SEV score less than 7 (moderate habitat degradation; impact on homing), in-stream work to repair a failed containment structure would likely have to be restricted to less than 4 hours.

Similar analyses were conducted for individual streams to be crossed in each watershed that provide critical habitat and fresh water EFH for SONCC coho salmon. Based on stream width-specific durations of exposure to TSS (table 3.5.3-21) and the minimum TSS concentrations and concomitant maximum distances downstream produced by fluming or dam-and-pump to equate to specific SEV scores (table 3.5.3-22), the greatest risk to SONCC coho would be 1,919 m downstream during fluming in streams >25 but ≤50 feet wide within the Little Butte Creek watershed (in Salt Creek) and 1,394 m downstream during fluming streams >10 but ≤25 feet wide within the Shady Cove-Rogue River watershed (in Indian Creek, table 3.5.3-23). At those distances, SEV = 4, causing a short-term reduction in feeding rates and/or short-term reduction in feeding success for juvenile or adult coho within the distances.

a/ Risks from downstream TSS by crossing all streams with bedrock substrate are considered None to Low; risks of downstream TSS crossing intermittent streams are considered None to Low; risks from downstream TSS by crossing perennial streams are considered Moderate to High.
b/ Highest SEV scores for each given crossing method and stream width category in specific watershed provided in table 3.5.3-22
c/ Distance for confluence of nearest neighbor stream with coho stream is assumed to be the same as the distance between the two stream crossing sites, forming an equilateral triangle.

The possibility for known or assumed salmon-bearing streams to be affected by TSS generated during dry open-cutting neighboring streams was also explored at the request of NMFS (2017i). Distances of nearest neighboring streams from each salmon-bearing stream are included in table 3.5.3-23. Nearest-neighbor streams are only considered for effects if they are within the same fifth field watershed as the targeted stream. Distance for the confluence of a nearest neighbor stream with a coho-bearing stream is assumed to be the same as the distance between the two stream crossing sites, forming an equilateral triangle. For each neighboring stream, downstream distances for TSS concentrations that produced the highest SEV score were computed with the same procedure described and available in table 3.5.3-22. If a nearest neighbor stream had bedrock substrate, dam-and-pump crossing was assumed, otherwise a flumed crossing was assumed. If the nearest neighbor distance to a salmon-bearing stream exceeded the maximum distance with highest SEV score downstream from the neighbor stream, then "None-Low" of TSS to the salmon-bearing stream produced during construction of the neighboring stream is assumed. In table 3.5.3-23, the nearest neighbor to the Rogue River is 5,248 m away which is with the downstream distance of 5,667 m at which the TSS concentration would cause a SEV score of 2 during construction across that nearest neighbor stream. Consequently, there would be no effects from crossing the nearest neighbor stream to the Rogue River. In table 3.5.3-23, risks from downstream TSS by crossing any stream with a bedrock substrate are considered "None-Low" because fine sediment (silt and clay) would not be mobilized in the water column; risks of downstream TSS crossing intermittent streams are considered "None-Low" because those streams would likely be dry during the in-stream construction period (ODFW 2008); risks from downstream TSS by crossing perennial streams are considered "Moderate-High" because flowing water would be present at the time of construction. In all other cases, construction across nearest neighbors could generate some level of risk for elevated TSS concentrations in the known or assumed salmon-bearing streams crossed in the range of SONCC coho although no severity of ill effects would exceed SEV = 4 for sediment produced in a coho-bearing stream by crossing a nearest neighbor stream. However, the estimated TSS concentration at any nearest neighbor tributary confluence would be diluted by greater flow rates and water volumes in larger receiving streams occupied by coho and therefore the estimated SEV in the coho stream would be considerably less than at the confluence.

A similar analysis of sediment effects on EFH streams known to support SONCC coho that are not directly crossed by the Pipeline but have a tributary that would be crossed and which could have an effect on the EFH fish-bearing stream is provided in Section 4.2.3.2. However, conducting the analysis required a different methodology than used in the nearest neighbor analysis provided for SONCC coho, above.

Suspended Sediment - HDD

An HDD crossing would be used on the Rogue River at MP 122.7. An HDD involves drilling a pilot hole, then enlarging that hole through successive reaming. High pressure drilling fluids, usually consisting of a slurry made of bentonite clay mixed with water, would be jetted at the drill head to advance the hole. Pipe sections long enough to span the entire crossing would be staged and welded along the construction work area on the opposite side of the waterbody, hydrostatically tested, and then pulled through the drilled hole. The right-of-way between the entry and exit hole of an HDD would generally not need to be cleared or graded, except for the area of the guide wires, and direct impacts on the waterbody, adjacent riparian vegetation, and associated aquatic resources would be avoided through an HDD. An HDD should not result in an increase of suspended sediments into the stream crossed, unless there is an "inadvertent return" or release of drilling mud, as discussed below.

According to GeoEngineers' (2017h) Feasibility Analysis for construction using HDD across the Rogue River (see appendix E), the design length of the Rogue River HDD crossing is approximately 3,050 feet. The proposed entry point is located in a relatively flat, lightly wooded area east of Rogue River and west of Old Ferry Road, approximately 650 feet from the east river bank. The exit point and pipe-stringing area are located within uplands approximately 2,100 feet west of the river within a drainage basin that drains to the river south of the crossing. The HDD exit location was extended away from the west river bank to avoid affecting several roads including State Highway 62, which is between the river bank and the exit. .. The HDD design indicates 56 feet of streambed cover in the river channel over the pipe. Based on the evaluation, an HDD crossing is feasible from geologic, land use, and geotechnical perspectives.

A qualitative hydraulic fracture and drilling fluid surface release analysis to characterize the risk of hydraulic fracture and drilling fluid surface release was conducted. However, a numerical analysis was not conducted because the vast majority of the HDD path is located within bedrock, and the numerical analysis method (cavity expansion theory) generally applies to soil materials rather than hard rock. There is a relatively low risk of drill hole collapse along the portions of the HDD profile that are located within the bedrock, although there is a moderate risk for localized hole instability along the HDD profile, specifically within about 50 to 100 feet of the entry and exit points where the HDD profile passes through alluvial and colluvial soils, and the cover between the HDD profile and the ground surface is relatively thin. As is typical with most HDD installations, the risk of drilling fluid surface release within about 100 feet of the entry and exit points is relatively high (GeoEngineers 2017h). The potential disturbance of riparian vegetation at the Rogue River HDD would be limited to incidental trimming of vegetation using hand tools directly over the pipeline along an approximately five-foot-wide footpath. This minor clearing is required to facilitate the temporary deployment of HDD guidance (telemetry) cables along the ground during construction and to perform a leakage survey after installation and commissioning. This is a relatively small area along the riparian zone of any stream and would have minimal adverse effect on aquatic resources.

Inadvertent Release of Drilling Mud (Inadvertent Return)

The HDD installation method is considered an effective technique for avoiding in-stream impacts by eliminating the need for in-stream excavation (Reid and Anderson 1998; Reid et al. 2004). Even with this technique, there is a potential for impact as a result of the HDD process. Drilling requires use of a drilling mud for lubrication of the bit and removal of cuttings. A non-toxic, biodegradable bentonite clay mixture makes up drilling mud. Because the drilling mud is under pressure during drilling, if the bit encounters substrate fractures or channels, it is possible for bentonite to escape from the hole (termed an "inadvertent return"). Bentonite can escape to the surface through fractures in the drilled substrate.

Bentonite by itself is generally considered a non-toxic drilling mud (Breteler et al. 1985; Hartman and Martin 1984; Sprague and Logan 1979), although according to Reid and Anderson (1998), the toxicity of bentonite (sodium montmorillonite) in fresh water ranges from 5,000 to 19,000 ppm (mg/liter) based on 96-hour tests for LC50 (the concentration at which 50 percent of the test population dies after 95 hours of exposure) on rainbow trout. The toxicity classifications based on LC50 values ranged from “slightly toxic” (5,000 ppm) to “practically non-toxic” (19,000 ppm) (Reid and Anderson 1998). In other tests, toxicities to lake whitefish and rainbow trout demonstrated threshold concentrations of 16,613 and 49,838 ppm (mg/l), respectively (Reid and Anderson 1998). More recently, toxicity to rainbow trout (LC50, 96-hour) was reported to be 19,000 mg/l (ClearTech 2015). LC50 concentrations >10,000 ppm would be considered “practically non-toxic” (Reid and Anderson 1998)..

Bentonite, as with any fine particulate material, can interfere with oxygen exchange by the gills of aquatic organisms (EPA 1986). The degree of interference generally increases with water temperature (Horkel and Pearson 1976). Impacts would be localized and would normally be limited to individual fish in the immediate vicinity of the inadvertent return. The majority of highly mobile aquatic organisms, such as fish, would be able to avoid or move away from turbidity spots and plumes (Reid and Anderson 1999). Other less mobile or immobile organisms, such as mussels and other macroinvertebrates, would incur direct mortality. Bentonite can smother macroinvertebrates and adversely affect filter-feeders (Falk and Lawrence 1973 in Hair et al. 2002 and Land 1974 in Cameron et al. 2002). Bentonite can also exacerbate or enhance the effects of toxic compounds to fish and aquatic invertebrates if those compounds are present in aquatic habitats (Hartman and Martin 1984). Similar to other fine-grained particulates, bentonite in flowing water is more likely to remain in suspension longer than in standing water. Consequently, effects to coho salmon by a release of bentonite into a waterbody would ultimately depend on volume of the release, volume of water present, and current.

The effects of an in-stream inadvertent return on spawning habitat, eggs, and juvenile survival depend on the timing of the release. If spawning habitat is nearby, redds could be affected in the vicinity of inadvertent return (Reid and Anderson 1999). While spawning would not occur during the crossing, effects may possibly occur within the immediate future unless high flows flush residual bentonite from the spawning areas. During establishment of the spawning bed, a minor addition of sediment would likely be cleaned out by the female as part of the normal preparation behavior. However, a heavy sediment load dispersing downstream could settle into spawning beds and clog interstitial spaces, reducing the amount of available spawning habitat, which could be a limiting factor in areas of already reduced habitat. When redds are active, eggs could be buried, disrupting the normal exchange of gases and metabolic wastes between the egg and water (Anderson 1996). The impacts of sediment intrusion into the redd on larval survival are more severe during the earlier embryonic stages than following development of the circulatory system of larvae, possibly because of a higher efficiency in oxygen uptake by the older fish (Bash et al. 2001). Clogging of interstitial spaces also reduces cover and food availability for juvenile salmonids (Cordone and Kelley 1961). Benthic organisms, which coho salmon would feed on, could also be affected by burial. However, bentonite is more likely to stay in suspension than settle like common bottom sediment; therefore, in flowing water areas, effects to benthic organisms from burial due to inadvertent return are likely to be low. The location where any inadvertent return may occur is the Rogue River, which would be affected less because of the dilution factor of large volume of water from any spill.

Reid and Anderson (1998), the Canadian Pipeline Water Crossing Committee (1999), and Reid et al. (2008) reported that 13 of 30 HDD stream crossings had drilling mud releases (citing Harder Associates 1996). The statistic is based on drilling mud releases during the early days of HDD technology (first conducted in 1971). The summary by Reid and Anderson (1998) provides a substantive description of the causes of inadvertent returns and subsequent effects to streams and habitat; drilling mud releases during HDD construction can result from:

1. Circulation losses through highly permeable gravels;
2. Mud migration along rock joints or fractures that intersect with the river bottom;
3. Loss of pilot hole directional control resulting in the intersection with the river bottom or approach slope;
4. Drilling mud pressures exceeding ground stress, widening existing or creating new fractures (hydraulic fracturing), allowing for mud migration;
5. Substantially different elevations of entry and exit drill locations. Resulting pressure head differences can cause substantial upland leakages of drilling muds once the drill bit nears the ground surface or when it breaks the surface.

Drilling mud releases may surface through river and streambeds, wetland bottoms, or at upland locations. The volume of mud released to the surface would depend on:

1. Porosity of the substrate transporting the mud;
2. Extent and size of the porous material;
3. Pressure exerted on the mud by the hydraulic system;
4. Viscosity of the mud at the time of exposure;
5. Whether mud circulation can be maintained.

Magnitude of effects by mud releases to fish, streams and habitat would depend on the following (page numbers referenced from Reid and Anderson, 1998):

1. Toxicity of the drilling mud components and additives (pages 57-59; also Table 1);
2. Increased sediment loads (page 59);
3. Effects to hydrological conditions that would cause poor conditions for wetland plant establishment and growth (pages 59-60);
4. Release into streams and rivers could cause increases in the downstream drift of stream macroinvertebrates (page 60);
5. Level of exposure to fish (e.g., concentration), duration of exposure, lifestage of fish present, timing of release, and ability of the watercourse to remove or incorporate the released muds without degrading existing habitats (page 61).

The report by Reid and Anderson (1998) summarizes the general effects, known or hypothesized, associated with drilling mud releases, but does not provide specific effects associated with each of the 13 instances cited.

Likewise, Canadian Pipeline Water Crossing Committee (1999) reported that drill mud seepage occurred in 36 of 146 cases of HDD cases reviewed with most significant leakage occurring at the drill entry or exit points due to different pressure heads with large differences in elevation between the two points. Leakage also occurred during reaming or pull-back. However, the report did not describe the effects to fish, streams and habitat in the cases with leakages or inadvertent returns. Potential inadvertent returns are more common near the HDD drill entry and exit locations; however, impacts to waterbodies are minimized by locating the drill entry and exit points away from the waterbody. The probability of an inadvertent return may increase when the drill bit is working nearest the surface (see GeoEngineers 2017h) but is dependent on numerous factors including substrate characteristics, head pressure of the drilling mud, topography, elevation, and subsurface hydrology. PCGP has proposed an HDD crossing of the Rogue River and designed this crossing such that areas of greatest risk from inadvertent return are on uplands and not adjacent to the waterbodies where much greater depth would be achieved and inadvertent return potential reduced.

Hydraulic fracture typically occurs when the drill path passes through relatively weak cohesive soils with low shear strength or very loose granular soils. Loose and silty sands and soft to medium-stiff silts and clays typically have a higher hydraulic fracture potential. Medium dense to dense sands and gravels and very stiff to hard silts and clays have a low to moderate hydraulic fracture potential. Unfractured rock, because of its high shear strength, typically has a low potential for hydraulic fracture. HDD installations with greater depth or in formations with higher shear strength may reduce the potential for hydraulic fracturing (see appendix E).

In the event an inadvertent return occurs into the river, drilling fluid would enter the waterway causing short-term, temporary water quality impacts downstream of the Pipeline project area including sedimentation and turbidity. In the event drilling fluid is inadvertently released into the river, the behavioral avoidance response of SONCC coho is presumed to be triggered within the immediate vicinity of the release, and the fish are expected to return and utilize the affected area shortly after the inadvertent release has been halted. PCGP developed its *Drilling Fluid Contingency Plan for Horizontal Directional Drilling Operations* (see appendix D), which describes how the drilling operations would be conducted and monitored to minimize the potential for inadvertent drilling mud releases. The HDD Contingency Plan also includes procedures for cleanup of drilling mud releases. If significant concentrations are found during monitoring as a result of a release, the following possible corrective measures would be taken:

- Deployment of containment structures, if feasible, and removal of drilling mud from substrate and streambanks, if possible.
- Increase the drilling fluid viscosity in an attempt at sealing the point at which fluid is leaving the drilled hole. The drilling operation may be suspended for a short period (i.e., overnight) to allow the fractured zone to become sealed with the higher viscosity drilling fluid.
- If increasing the drilling fluid viscosity is ineffective, lost circulation materials (LCM) may be introduced into the hole by incorporating them in the drilling fluid and pumping the material down-hole. The drilling operation may again be suspended for a short period (i.e., overnight) to allow the fractured zone to become sealed with the lost circulation materials.
- Depending on the location of the fractured zone, a steel casing may be installed that is of sufficient size to receive the largest expected down-hole tools for the crossing. This casing installation provides a temporary conduit for drilling fluids to flow while opening the remaining section of the hole to a diameter acceptable for receiving the proposed pipe sections. To alleviate future concerns with the steel casing after the HDD installation is completed, the casing is generally extracted from the hole prior to or just after completing the HDD installation. However, there have been instances when attempts at extracting the steel casing were unsuccessful.
- In the event drilling fluid flow is not regained through the annulus of the drilled hole and a steel casing installation is not utilized, the HDD contractor may elect to install a grout mixture into the drilled hole in an attempt to seal the fractured zone. The down-hole drilling assembly is generally extracted, and the existing hole is re-drilled to the point at which it had previously been drilled prior to having encountered the loss of drilling fluid.

- In addition, a grouting program may be implemented from the surface in the event that the installation of grout into the drilled hole is unsuccessful. This approach is only practical in areas where drilling rigs with vertical drilling capabilities can access the HDD alignment. If a surface grouting program is utilized, the HDD drilling assembly is extracted from down-hole. Multiple holes are then drilled vertically on either side and along the HDD alignment to allow for grout slurry to be pumped into the fracture zone where the drilling fluid had previously been lost from the drilled hole. This process can take several days to complete in order to insert the grout in a grid pattern that covers the full fractured zone, during which time the HDD operation is suspended. Upon completion of the surface grouting program, the HDD operation would resume and the pilot hole would be reestablished through the grouted formation.

In some instances, it may be determined that the existing hole encountered a zone of unsatisfactory soil material, and the hole may have to be abandoned. If the hole is abandoned, it would be filled with cuttings and drilling fluid.

Overall at the site of any inadvertent return, the amount of drilling mud released into a waterbody would be low. The HDD location on the Rogue River has large volumes of water and swift flows, where the drilling mud would be diluted. In the unlikely event of an inadvertent release of drilling mud from an HDD in the Rogue River, there would be minor short-term adverse effects to aquatic resources including coho salmon.

Suspended Sediment – Conventional Boring

A direct bore method would be used at crossing of the Medford Aqueduct Ditch at MP 133.7. There are different kinds of boring methods, including jack and bore, slick bore, and hammer bore. The type of method to be used at specific locations has not yet been determined by PCGP. During a standard boring operation, pits are excavated on both ends, with spoil from the bore passed into the pit and removed by trackhoe. The walls of the bore pits may have to be supported by trench boxes or metal sheet piling. If groundwater seeps in to the bore or bore pits, a dewatering system would need to be used. Pipe would be welded in the pit, and passed through the bore hole. Bores should not result in increasing suspended sediments into the streams crossed. Although there may be some risks of failure associated with conventional boring (examples include cobble, gravel other substrates incapable of supporting the bore hole, deflection of the bore by undetected buried wood or boulders, and high water tables risking collapse of bore work pits), taking into consideration that the crossing is at an aqueduct that does not contain the listed coho salmon and that active BMPs and monitoring would be used during crossing operations, no adverse effects are expected to occur to SONCC coho from the direct bore even if some boring mishap were to occur.

Movement Blockage

Of the 13 waterbodies with confirmed or assumed presence of SONCC coho salmon, all but one (Rogue River) will be crossed by dry open-cut. Dry open-cut construction is expected to block upstream movement by adult salmonids, as well as within stream movements of juvenile coho. Restrictions on migration could occur from short-term elevation of sediment and method of water diversion around the stream crossing area. As discussed above, fish are expected to abandon cover and/or avoid turbidity plumes generated by in-stream construction. In-stream construction would be completed prior to most upstream migrations by SONCC coho.

In addition, block nets would be employed at all waterbody crossings in which water is present at the time of construction. Procedures to exclude fish from the construction right-of-way, maneuvering fish downstream of the crossing site, isolating and dewatering the construction site, removing fish from within the isolated construction site during dewatering, fish handling, holding and release, and monitoring with documentation are described in the Fish Salvage Plan in appendix T. The Fish Salvage Plan was reviewed by BLM, Forest Service, and Bureau of Reclamation, and each agency submitted documentation to PCGP stating that the plan was complete.

Flumes would maintain streamflow and fish might move upstream or downstream through the flume. With the dam and pump method, coho would not be able to move upstream or downstream through the work area until the dams have been removed. Flumes and isolation structures (e.g., dams) would be removed as soon as possible following backfilling of the trench. Overall, the presence of temporary physical structures would not cause meaningful delays to adult upstream migrating coho salmon resulting in unsubstantial affects to coho salmon individuals.

Newcombe and Jensen's (1996) Severity of ill Effect (SEV) scale includes avoidance behavior (SEV = 3), a behavioral effect that changes the activity patterns or alters the kinds of activity usually associated with an undisturbed environment (Muck 2010) and may indicate juvenile and/or adult coho instream movements would be affected. Likewise, an SEV score of 3 indicates a "measured change in habitat preference" in models developed by Anderson et al. 1996. SEV scores of 3 and higher due to elevated TSS concentrations are assumed to block or interfere with fish movements during durations of exposure to the suspended sediment downstream (provided in table 3.5.3-21). Downstream distances at which SEV $\geq$ 3 during fluming or dam-and-pump construction in each 5th field watershed were provided in table 3.5.3-22.

Entrapment

Waterbody crossings using the "dry" crossing methods, flume or dam-and-pump, may result in some fish being entrapped in streams. Flumes and dams would be completely installed and functioning before any in-stream trenching disturbance occurs. Construction across a waterbody would take up to four days using dry open-cut methods, but less for small and intermediate streams.

For typical crossings, once streamflow is diverted through the flume pipe or pumped drains, but before trenching begins, fish trapped in any water remaining in the work area between the dams would be removed and released (salvaged) using the *Fish Salvage Plan* (see appendix T). Salvage methods could include seines, and/or dip nets and electrofishing (see Conservation Measures). Seining would be the primary method used to salvage fish but electrofishing methods may be used if all fish cannot be removed from the area potentially dewatered (see appendix T). All methods of capture and holding have risks of stress, injury, or mortality of fish. Fish inadvertently left within the dammed-off construction zone could be killed by impingement on pump intakes used to dewater the construction zone or would likely die once all water was removed. To eliminate or greatly reduce these effects, PCGP would contract with either ODFW or a qualified consultant to capture the fish. Fish removal personnel would be approved by ODFW and NMFS for this listed species. Personnel that would handle and/or remove fish on federal lands would also be approved by the Forest Service or the BLM or be done directly by agency personnel if approved by ODFW. Overall, some listed juvenile fry coho salmon are likely to suffer injury or mortality, but with the implementation of project conservation measures the numbers would be slight.

There are 70 waterbodies that would be crossed by dry open-cut procedures in the Upper Rogue Subbasin (table 3.5.3-3), including 13 with bedrock streambeds that may necessitate blasting and/or use of mounted impact hammers (discussed above under Acoustic Shock). However, only seven of these are known to support SONCC coho, and five others are assumed to be occupied by coho. The 12 streams (see table 3.5.3-23, excluding the Rogue River) include three in the Trail Creek watershed, one in the Shady Cove-Rogue River, two in the Big Butte Creek watershed, and six in the Little Butte Creek watershed.

The width of the construction right-or-way across waterbodies would either be 75 feet or 95 feet. Fish would be salvaged from within the 75-foot or 95-foot wide right-of-way crossing of each stream where blasting is not expected. The fish salvage area would be isolated by sand bag dams installed upstream and downstream from the centerline.

Estimates of juvenile fry coho present in at crossing sites in streams were based on all rights-of-way being 95 feet wide at each stream crossing within which coho would be salvaged. Numbers of juvenile fry coho potentially present or assumed to be present in the streams with crossed by dry open-cut (no blasting) are provided in table 3.5.3-24 and do not include numbers within streams with bedrock substrates that were provided in table 3.5.3-11. In the 10 waterbodies known or assumed to be inhabited by SONCC coho, 167 juvenile fry coho would be displaced and or salvaged prior to construction, which does not include the 67 juvenile fry coho that would be salvaged from streams with bedrock prior to blasting (table 3.5.3-11). The estimates in table 3.5.3-24 are based on no fish being herded out of the work area prior to dewatering (see Fish Salvage Plan). The actual number that would be salvaged is expected to be much less.

TABLE 3.5.3-24

Worst Case Estimates of Juvenile Fry Coho Present or Assumed as Present at Streams Crossed by Dry Open-Cut (No Blasting Assumed) and Juvenile Fry Salvaged Prior to Construction of the Pipeline Project within the SONCC ESU

Subbasin and Fifth-Field Watersheds	Dry Open-Cut w/ Juvenile Fry Coho Present, Assumed	Juvenile Fry Present at Each Crossing a/	Total Juvenile Fry Present b/	Juvenile Fry Salvaged at Each Crossing c/	Total Juvenile Fry Salvaged d/
Upper Rogue Subbasin					
Trail Creek	1	17	17	17	17
Shady Cove-Rogue River	1	15	15	15	15
Big Butte Creek	2	17	34	17	34
Little Butte Creek	6	17	101	17	101
TOTAL	**10**		**167**		**167**

a/ Juvenile Fry Present at Each Crossing based on Juveniles per Mile (see table 3.5.2-5) within a stream crossing length of 95 feet (worst case, see text).
b/ Total Juvenile Fry Present (worst case) = number of Juvenile Fry Present at Each Crossing multiplied by number of Dry Open-Cut crossings with Juvenile Fry Coho Present or Assumed.
c/ Juvenile Fry Salvaged at Each Crossing based on Juvenile Fry per Mile (table 3.5.3-5) within a stream crossing length of 95 feet (worst case, see text).
d/ Total Juvenile Fry Salvaged (worst case) = number of Juvenile Fry Salvaged at Each Crossing multiplied by number of Dry Open-Cut crossings with Juvenile Fry Coho Present. The estimate is based on no fish being herded out of the work area prior to dewatering (see Fish Salvage Plan). The actual number that would be salvaged is expected to be much less.

Riparian Vegetation Removal and Modification

Vegetated areas adjacent to waterbodies have been classified/defined in different ways depending on the resource and/or management objective being analyzed. Analyses conducted for SONCC coho have considered effects to riparian vegetation present within a one site-potential tree height (1SPTH) buffer on either side of a waterbody on both federal and non-federal lands. This analysis area was determined in discussions with NMFS, USFWS, and other federal agencies during Interagency Task Force meetings.

Riparian Reserves are areas that are managed to protect habitat for fish species, as well as other riparian-dependent plants and animals on federal lands (BLM and Forest Service lands). Riparian Reserves include areas that range in size from 1SPTH to 2SPTH buffers on either side of a waterbody, depending on the waterbody type. Analyses to coho salmon here do not consider effects to Riparian Reserves because those effects would be limited to certain federal lands and analyses provided below consider effects on all lands, hence the analysis of effects to Riparian Zones rather than to Riparian Reserves. This analysis considered all intermittent and perennial waterbodies crossed and adjacent to the Pipeline in the range of SONCC coho and also included waterbodies that are not assumed to have coho present.

Aquatic resources could be affected as a result of removal of vegetation and habitat at the waterbody crossing sites as required for construction. Short-term, physical habitat disruption would occur during trenching activities. Long-term degradation of habitats could occur if the stream contours are modified in the area of the crossing; the flow patterns are changed; and if erosion of the bed, banks, or adjacent upland areas introduces sediment into the waterbody. Loss of riparian vegetation along the banks would reduce shade, potentially increasing water temperatures, remove sources of terrestrial food for aquatic organisms, decrease LWD and the associated reduction in habitats, and potentially increase mass slope failures adjacent to waterbodies.

Much of the impact to coldwater anadromous and resident fisheries by past land uses have been alterations of riparian habitats by logging, road building, agriculture, or other developments such as residences and utility corridors. A total of 94.06 acres of vegetation with riparian zones one site-potential tree height wide (ranging from 159 feet wide for Trail Creek, to 157 feet wide for Shady Cove-Rogue River, 187 feet wide for Big Butte Creek, and 158 feet wide in Little Butte Creek watersheds) associated with waterbodies within range of SONCC coho ESU would be directly affected by all construction related activities. Less than half of the affected vegetation (41.59 acres) would be non-forested vegetation, but 20.24 acres of late successional-old growth forest and 17.97 acres of mid-seral forest would be removed within riparian zones (see table 3.5.3-25a). As discussed in section 3.5.3.2, Habitat, and presented in table 3.5.3-8, the LWD components of most aquatic habitats in watersheds occupied by SONCC coho and crossed by the Pipeline are LWD-deficient and below benchmark conditions established by ODFW.

In forested habitats, conifer trees would be replanted within the construction right-of-way and TEWAs outside of the 30-foot-wide maintenance corridor, which would revert to their pre-construction state over time. The 30-foot-wide maintenance corridor centered over the pipeline would be maintained in an herbaceous/shrub state during the life of the Pipeline, assumed to be 50 years (see table 3.5.3-25b). Over the long-term, 5.02 acres through riparian late successional-old growth forest and 3.78 acres through mid-seral forest would be maintained in an herbaceous/shrub state within riparian zones associated with SONCC coho (see table 3.5.3-25b).

In areas of riparian vegetation, PCGP would neck down to a 75-foot-wide construction right-of-way at most waterbody crossings and maintain a setback between waterbody banks and TEWAs in forested areas. Following construction, PCGP would implement measures to replant native trees and shrubs where they had been before in riparian areas and would minimize vegetation maintenance by providing a riparian strip at least 25 feet wide to be permanently revegetated on private lands and 100 feet wide on federally-managed lands as measured from the edge of the waterbody. In forested areas, replanting of native trees would occur beyond the 25- and 100-foot-wide areas, respectively. Following planting, vegetation monitoring would occur for two to three years to ensure successful revegetation. If vegetation does not meet designated goals, additional planting would occur and monitoring would continue until the desired revegetation is achieved. Within the 30-foot-wide pipeline corridor, the plants would be maintained by periodic vegetation maintenance. As required by the FERC's *Upland Plan*, PCGP consulted with the NRCS, BLM, and Forest Service regarding specific seeding dates and recommended seed mixtures for the Pipeline project area (see PCGP's Resource Report 7). The recommendations have been incorporated into the Pipeline project-specific ECRP (see appendix F). The ECRP describes the procedures that would be implemented to minimize erosion and enhance revegetation success for the entire Pipeline project.

For the Rogue River, which would be crossed by HDD, the potential disturbance in riparian areas would be incidental trimming of vegetation using hand tools directly over the pipeline along an approximately five-foot-wide footpath. This minor clearing is required to facilitate the temporary deployment of HDD guidance (telemetry) cables along the ground during construction and to perform a leakage survey after installation and commissioning. This is a relatively small area along the riparian zone of any stream and would have minimal adverse effect on aquatic resources.

Overall, restricting the low-growth vegetation area to a small portion of the total riparian right-of-way clearing would allow much of ecological function of the riparian conditions relative to coho salmon needs (e.g., shade, future LWD and organic input) to return more quickly. This would limit the overall long-term impacts of loss of riparian habitat to a small portion of each stream crossed reducing future negative effects to coho salmon resources. Some limited intermediate-term adverse effects to coho salmon habitat function would remain relating primarily to LWD reduction. The effects of riparian vegetation removal on water temperature and LWD is presented below.

A series of tables (M-2 through M-5, provided in appendix M) identify the areas (acres) of vegetation within riparian zones (1SPTH) affected by construction and operation of the Pipeline project across or adjacent to waterbodies with expected Oregon Coast and SONCC coho presence, by 5th field watershed. The tables identify general vegetation (forested by ageclass/ non-forested) within riparian zones that would be affected from the Pipeline crossing the waterbodies or from waterbodies adjacent to the Pipeline, as well as identify the acres of vegetation affected within the riparian zone that is federally designated critical habitat. Tables M-2 and M-4 identify areas (acres) of vegetation affected within Riparian Zones of waterbodies known or suspected to have Oregon Coast coho salmon presence, and tables M-3 and M-5 identify acres of vegetated affected within Riparian Zones of waterbodies known or suspected to have SONCC coho salmon presence.

Effects to waterbodies and Oregon Coast and SONCC coho due to removal of riparian vegetation and maintenance within the construction and operation corridor adjacent to but not crossed by the Pipeline project would be similar to effects to riparian vegetation for streams crossed by the Pipeline:

- Loss of riparian vegetation along the banks would reduce shade potentially increasing water temperatures.
- Decreased LWD recruitment in streams and on adjacent uplands, although current conditions of LWD in 5th field watersheds crossed by the Pipeline are generally undesirable.
- Removal of an important source of terrestrial food for aquatic organisms.
- Potentially increase mass slope failures and/or erosion due to surface runoff adjacent to waterbodies that could increase sediment in the waterbody.

Where vegetation is cleared from the riparian zone of a waterbody not crossed but adjacent to the Pipeline, a vegetation buffer (of some width but less than 1SPTH) adjacent to the waterbody is expected to remain. Consequently, effects from the Pipeline would be even less than those described for riparian zones and associated waterbodies that would be crossed. Riparian vegetation within 1SPTH that would be maintained in a herbaceous state within the 30-foot maintenance corridor during the life of the Pipeline is included in tables M-4 and M-5; the majority of riparian vegetation affected by the Pipeline is associated with waterbodies crossed by the right-of-way (61 percent with potential Oregon Coast coho presence and 81 percent with potential SONCC coho presence) not riparian vegetation associated with waterbodies adjacent to the right-of-way.

a/ Considers terrestrial habitats that were present prior to construction within the 30-foot wide maintenance corridor.

b/ Includes riparian zones of adjacent streams within the construction right-of-way that are not crossed but listed in table 3.5.3-3 and streams off the right-of-way, not included in table 3.5.3-3.

c/ Habitat Types within Riparian Zones generally categorized as: Late Successional (Mature) or Old Growth Forest (coniferous, deciduous, mixed ≥80 years old); Mid-Seral Forests (coniferous, deciduous, mixed ≥40 but ≤80 years old); Regenerating Forest (coniferous, deciduous, mixed ≥5 but ≤40 years old); Clearcut Forests; Forested and Nonforested Wetland, Unaltered Nonforested Habitat (grasslands, sagebrush, shrublands), Agriculture and Altered Habitats (urban, industrial, residential, roads, utility corridors, quarries).

Water Temperature

Clearing the right-of-way would remove shading vegetation from uplands and riparian areas, exposing the land and water to increased sunlight, potentially resulting in direct increases in water temperatures. Additionally, indirect increases in stream water temperatures may occur as water flows over the warmer land surface and eventually reaches the waterbody (Beschta and Taylor 1988).

The effects of water temperature on salmonid life stages have been extensively reviewed by McCullough (1999) and Richter and Kolmes (2005). Maximum water temperatures ranging from 22 to 24°C (71.6 to 75.2°F) limit distribution of many salmonid species. No salmonids can survive water temperatures exceeding 25°C (77°F) for extended periods (Ice 2008). High water temperatures can cause migratory species (including anadromous salmonids) to delay upstream migration (Bjornn and Reiser 1991), can decrease survival of spawners by increasing metabolic rates (Ice 2008), and can positively influence rates of embryo development and emergence but negatively influence dissolved oxygen concentrations, which alternatively limit rates of embryo development (Bjornn and Reiser 1991). High temperatures inversely influence solubility of oxygen in water (Ice 2008) so that introduction of organic matter with decomposition by microorganisms reduces dissolved oxygen, exacerbated by high temperatures. Along with increased fines (suspended silt and clay) and decreased relative rate of oxygen input to water (reaeration) through reduction in stream flows (Ice 2008), high temperatures can adversely affect various salmonid life stages. Coho upstream migration water temperature requirements range from 7.2 to 15.6°C (46.0 to 62.1°F), spawning requirements from 4.4 to 9.4°C (42.9 to 52.9°F), and for incubation from 4.4 to 13.3°C (42.9 to 61.9°F); preferred temperature is 12.1°C (60.8°F) and upper lethal temperatures range from 26.0 to 28.8°C (86.8 to 92.8°F), depending on previous acclimation temperatures (Bjornn and Reiser 1991).

Vegetative cover that provides shade, especially during summer, is one factor that regulates water temperature. Construction across waterbodies would necessitate removal of trees and riparian shrubs at the crossing locations that may influence stream temperature. Available information on the effects of pipeline construction in other regions on water temperature has found no or immeasurable change in temperatures. The total width of riparian area affected by shade tree removal would be small (less than 100 feet) relative to the length of any stream crossed. In one study, construction across two coldwater, fish-bearing streams in Alberta required removing forested riparian vegetation; water temperatures at construction sites and downstream did not increase above temperatures at control sites upstream from construction (Brown et al. 2002). In the Alberta study, the highest water temperature recorded was 66°F (19°C in August). In the New York study, the highest temperature was 79°F (26°C) sometime between August and October. Similarly, water temperatures measured at four coldwater streams in New York before and during pipeline construction and for three years following construction showed no short- or long-term effects on water quality parameters, including water temperature, even though such effects were expected because streambank vegetation had to be cleared, which reduced shading (Blais and Simpson 1997).

Another recent right-of-way clearing study in Oregon found little to no effect from existing and proposed right of clearing on coldwater Cascade mountain streams (Tetra Tech 2013). Monitoring of 22 existing cleared right-of-ways for transmission lines in the Cascade region along the upper North Santiam River averaging 244 feet wide found no significant temperature (peak daily average, and daily maximum) change across the clearings compared to existing uncleared areas on each of these streams. While temperature changes did occur across the clearing (average of peak daily maximum change 0.19°F/100 feet of stream), these increases were no different from the temperature changes in the uncleared wooded areas just upstream of these clearing. While these streams did retain some vegetation in the right-of-way, they were kept relatively low to ensure no issues with the power lines. Modeling of these streams using the Stream Segment Temperature Model (SSTEMP; Bartholow 2002) estimated some relatively small increases, which were generally greatest for smallest streams. The model assumed all or most vegetation would be removed from banks over a 150-foot-wide projected clearing. The results for both existing (summer 2012) and projected worst-case (likely maximum summer air temperature) environmental conditions with very conservative shade assumptions (0 and 25 percent for entire 150-foot clearings) showed an average increase of about 1.1°F (median of about 0.4°F) in the modeled maximum and maximum daily mean temperature across the assumed future clearing of these 22 streams. The small size of the streams in this study affected the model results. All but three of the streams had flow less than 1 cfs and width less than 10 feet. The three larger streams had modeled maximum temperature changes ranging from 0.0 to 0.2°F. Most of these streams had relatively low to moderate temperatures (mean maximum about 55°F); therefore, these low temperature increases were generally not expected to affect fish resources (Tetra Tech 2013).

Following requests by the Forest Service, PCGP had temperature models run by North State Resources (NSR) on six different stream segments on NFS lands in the Umpqua River basin on tributaries to East Fork Cow Creek (five crossings) and on the upper Rogue River basin on Little Butte Creek (NSR 2009). While not all of these streams are in the range of SONCC coho salmon, they are suitably representative of likely temperature changes that could be expected of streams of similar characteristics (i.e., width, flow, slope, vegetation, etc.) in regions where the ESU is located using these model parameters. Of the three smallest streams (with base flows <0.1 cfs, widths ≤3 feet), modeled average temperature increases ranged from 1.0 to 8.6°C (1.8 to 15.4°F) right after construction. Because these streams were so small they likely also would have temperatures reduced rapidly downstream of the clearing from ground water inflow and likely would have no measurable effects on streams they flow into downstream. The two five- and six-foot-wide streams would have estimated maximum increases ranging from 0.4 to 0.5°C (0.7 to 0.9°F) with maximum temperature remaining at or below 15.6°C (60.1°F) in these two streams just downstream of the crossing. These temperatures would remain well within suitable range for salmonids. The largest stream (22 feet wide) increase was estimated to be 0.02 to 0.1°C (0.04 to 0.2°F) depending on the temperature model. The modeled results, based on assumptions used about rate of vegetation regrowth, found that most temperature increases remained within the first 5 years but were approaching pre-project temperatures within 10 years. Conditions at other streams along the pipeline route may vary from these due to site-specific differences, but these results may be fairly representative of changes that may occur at forested streams along the route. Overall results suggest that, other than the very smallest streams where fish resources would be limited, changes in temperature from vegetation removal are likely to remain small and immeasurable having unsubstantial effects on fish resources.

Similarly, GeoEngineers (2017c) modeled thermal impacts within 4th Field Watersheds where streams would be crossed by the Pipeline where riparian shading vegetation would be removed within the 75-foot wide construction corridor and would be affected within the 30-foot maintenance corridor over the long-term (see table 3.5.3-25b, above). Model results show a maximum predicted increase of 0.16°C at one 75-foot clearing. The analysis showed that elevated water temperatures would return to ambient levels within a maximum distance of 25 feet downstream of the pipeline corridor, based on removal of existing riparian vegetation over a cleared corridor width of 75 feet (GeoEngineers 2017c). The results are similar to the more geographically-limited results obtained by North States Resources (NSR 2009), which suggested more thermal impact. The conclusion drawn by GeoEngineers (2017c) was that the magnitude of thermal impact caused by construction would not be expected to cause a thermal barrier to fish migration.

GeoEngineers (2017c) used the SSTEMP model by Bartholow (2002) to estimate potential temperature effects at 15 proposed crossing locations (each a 75-foot-wide clearing) along the whole route. A total of 12 of these were in the watershed range of Oregon Coast coho salmon ESU and two were in the range of SONCC coho salmon ESU. These sites would be generally representative of watershed habitat conditions where project area coho salmon may be present along the project route, although not necessarily where coho salmon are directly present. The streams selected varied from 2 to 85 feet wide (average 29 feet), moderately large streams, with only eight of these having a less than 10-foot flowing width. Conditions modeled were based on conditions measured during late August 2010 and did not consider maximum potential air temperatures though they were likely representative of summer conditions. The average modeled increase for these 15 streams was 0.03°F, and the maximum increase among the streams was 0.3°F. Overall, these estimated changes are relatively low. They are lower than the NSR (2009) estimates for one comparable stream, but model conditions were slightly different. The GeoEngineers model assumed a 75-foot-wide clearing, whereas the NSR model assumed a 95-foot-wide clearing and other parameter differences that would contribute to the different results.

As a rule, the effect of water temperature of a non-fish-bearing tributary on water temperature of a fish-bearing receiving stream is determined as the weighted mean of the two water temperatures, weighted by respective volumes or in-stream flows. If T_1 = temperature of tributary with F_1 = flow rate, and T_2 = temperature of receiving stream with F_2 = flow rate, then the resulting water temperature T_R at the confluence of the two waterbodies would be:

$$T_R = (T_1\ F_1 + T_2\ F_2) / (F_1 + F_2)$$

For example, Hydrofeature N is an unnamed tributary to East Fork Cow Creek crossed at MP 111.01. Pipeline construction would increase the water temperature by 8.6°C (15.5°F) from its base temperature of 11°C (51.8°F) (see NSR 2009). The water temperature would be increased to 19.6°C (67.3°F), but its reported summer base flow is 0.002 cfs. ODEQ measured water temperature within East Fork Cow Creek during September 1998, reported at 13.5°C (56.3°F). No in-stream flow data are available for East Fork Cow Creek, but the USGS (Gage 14309500) has measured flows in West Fork Cow Creek, reporting an average flow of 11.4 cfs during September. Using those data to illustrate how water temperatures would be combined by the weighted average, the resulting water temperature of Hydrofeature N and the receiving stream would be T_R = (19.6°C x 0.002 cfs + 13.5°C x 11.4 cfs) / (0.002 cfs + 11.4 cfs) = 13.501°C (56.302°F). The increase of water temperature in the receiving stream by the tributary water temperature would be immeasurable [in this illustration the increase would be 0.001°C (0.002°F)].

PCGP has proposed supplemental riparian plantings as outlined in the ECRP (see appendix F) to help ensure that the core cold-water habitat temperature criteria are not exceeded at the maximum point of impact. These measures are designed to speed up the rate of riparian area recovery and provide more effective shade immediately following construction. Much of the riparian area would be allowed to regrow from plantings with herbaceous plants (only 10 feet wide would be maintained without some growth) and conifer and other trees (all but 30-foot width). On small streams and to a lesser extent on larger streams, even 10- to 15-foot-high trees would supply shade, reducing solar heating effects on streams. Thus, plantings and vegetation regrowth in riparian areas would help moderate potential temperature increases in the short-term (a few years). PCGP would install supplemental transplanted trees on the Umpqua National Forest within the riparian areas of East Fork Cow Creek (i.e., 15 to 20 feet tall with full crowns) to increase riparian area canopy closure and placing LWD and boulders to create micro-topography within the wetted stream channel (see the ECRP). Shading from transplanted vegetation and micro-topographic features incorporated into the final grading plan are likely to reduce the heat load enough to reduce the likelihood of measurable water temperature increases. PCGP modeled the potential benefit of post project effective shade created by these mitigation measures on the Umpqua National Forest. The results of the 10-year post-project modeling time step was used to predict the benefits of the mitigation measures because the trees that would be transplanted provide at least the same shade values as predicted for this time step. The predicted water temperature changes are small, with less than a 0.3°C (0.5°F) change at the point of maximum impact, with no increase at the stream network scale (NSR 2009). Thus, based on the model, the slight effects of solar heating from clearing would gradually be reduced or completely eliminated over time, at most between 5 and 10 years. Inclusion of the measures improves the certainty that riparian area clearance and stream channel disturbance activities within the construction right-of-way would not cause measurable water temperature increases at the maximum point of impact or at the stream network scale.

Based on available information, any changes in water temperature related to the 75-foot-wide right-of-way vegetation clearing at waterbody crossings are likely to be very small and undetectable through measurements, except for possibly the very smallest and often intermittent flowing streams. Any temperature changes that may occur would gradually be reduced or eliminated over time as most riparian vegetation, from plantings and natural vegetation growth, increases in size and thus increases stream shading. Adverse effects on coho salmon resources along the route would be discountable due to limited distribution of any measurable changes to regions within the 13 waterbodies with confirmed or assumed presence of SONCC coho.

Large Woody Debris

A potential effect on fisheries that would result from forest clearing at pipeline crossings of waterbodies is the reduction of LWD in streams and on adjacent uplands (Harmon et al. 1986; Sedell et al. 1988). Large logs provide in-stream hydraulic complexity, which contributes to habitat complexity and the formation and maintenance of pools, riffles and other habitats which are critical to salmonid spawning and juvenile rearing. As the size of individual logs or accumulations of logs increases, the size and stability of pools that are created also increase (Beschta 1983). Riparian forests that undergo harvesting of large trees take on secondary-growth characteristics and contribute lower quantities of woody debris than unmanaged, old-growth forests (Bisson et al. 1987). However, sufficiently wide, carefully managed riparian buffers that retain a full complement of ages, sizes, and species of native trees and vegetation can ensure adequate recruitment of LWD to streams (Bisson et al. 1987; Murphy and Koski 1989).

Existing conditions associated with riparian vegetation within all fifth-field watersheds in the Upper Rogue Subbasin crossed by the Pipeline (see discussion related to table 3.5.3-8) are generally undesirable. Streams in the watersheds are deficient in numbers of LWD pieces per length of stream channel, in volume of LWD, and in numbers of key pieces (60 cm or greater in diameter by 12 meters or greater in length) per unit of stream length. There are too few large conifers along most stream reaches and LWD numbers, volume, and presence of key pieces tend to be below benchmark levels. The Pipeline project would remove 18.08 acres of late successional-old growth (LSOG) forest and 17.47 acres of mid-seral forest within riparian zones in watersheds occupied by SONCC coho (see table 3.5.3-25a), which would affect recruitment of LWD at those sites. Of the total riparian forest affected (including regenerating forest stands), 6.11acres would be removed in the Trail Creek watershed, 7.93 acres within the Shady Cove-Rogue River watershed, 4.80 acres within the Big Butte Creek watershed, and 19.97 acres within the Little Butte Creek watershed.

PCGP has proposed to use on-site mitigation for impacts to waterbodies by installing LWD at agency and land owner-approved and appropriate areas within the construction right-of-way across certain waterbodies (see section 3.5.3.4, Conservation Measures). The use of LWD as a mitigation measure for impacts associated with in-stream construction has been documented as an effective means of creating in-stream habitat heterogeneity, reducing streambank erosion, reducing sediment mobilization (Bethel and Neal 2003), and enhancing local fish abundance (Scarborough and Robertson 2002). Placement of LWD on the streambanks and in the streams can provide slight shade and increase bank stability while vegetation is maturing following construction. Additionally, placement of LWD in streams or on streambanks can provide habitat as substrate for benthic invertebrates, an important food source for salmonids and also increase habitat for forage species with the creation of pools and enhancement of the salmonid rearing potential of an area (Cederholm et al. 1997; Slaney et al. 1997). Long-term losses of LWD input would largely be mitigated through riparian replanting of conifers in the right-of-way as discussed under Riparian Vegetation and Removal above. While there may be some reduction in total stream LWD between short and long-term, the amount would be relatively small considering that, at most, 75 to 95 feet of the channel would be affected and that mitigation and enhancements would be implemented (see section 3.5.3.4, Conservation Measures). As a result, LWD changes would result in only minor intermediate-term adverse effects to SONCC coho salmon.

<u>Streambank Erosion and Streambed Stability</u>

The clearing and grading of vegetation during construction could increase erosion along streambanks resulting in higher turbidity levels in the waterbodies crossed. Alteration of the natural drainage ways or compaction of soils by heavy equipment near streambanks during construction may accelerate erosion of the banks, runoff, and the transportation of sediments into waterbodies. Streambank erosion, sedimentation, and higher turbidity levels related to the Pipeline project could affect aquatic resources, as discussed above. The degree of impact on aquatic organisms due to erosion would depend on sediment loads, stream velocity, turbulence, streambank composition, and sediment particle size.

The rootwad network of trees adjacent to stream supplies bank stability. Those networks within 25 feet of the stream are considered most important at providing the root source aiding in bank stability (WDNR 1997). To aid in maintaining this bank stability, PCGP would cut most trees near the bank, except those in the trench line, at ground level, leaving the root systems in place helping to maintain riparian stability. Roots would be removed over the trench line or from any steam banks that would need to be cut down or graded to accomplish the pipeline crossing.

To minimize these impacts, PCGP would use temporary equipment bridges, mats, and pads to support equipment that must cross the waterbody (perennial, intermittent, and ephemeral if water is present) or work in saturated soils adjacent to the waterbody. PCGP would also install sediment barriers, such as silt fence and straw/hay bales, across the right-of-way at the edge of waterbodies throughout construction except for short periods when the removal of these sediment barriers is necessary to dig the trench, install the pipe, and restore the right-of way. Practices to minimize streambank erosion are provided in the ECRP (see appendix F).

The FWS expressed concerns that more detailed site-specific information on bank material, streambed composition, shoreline vegetation and other information is needed to adequately ensure that actions occurring at a stream crossing do not significantly increase streambank erosion and streambed instability. PCGP, in response to these requests, conducted an initial assessment of crossing conditions of all streams suitable for analysis based on the FWS risk matrix (GeoEngineers 2017d). GeoEngineers, using a combination of field and GIS data, rated proposed stream crossings based on the matrix along the entire route including 20 streams in the range of SONCC coho, included in table 3.5.3-3. Each crossing was rated as low, medium, or high for each of the two axes based on the Pipeline impact potential at the crossing and the relative stream response potential at the crossing (all of the 20 stream crossings were placed into one of nine categories, such as Low–Low, Low–Medium, and Medium–High). Crossings of all streams except for Neil Creek were evaluated as having sensitive streambed, banks, or riparian revegetation conditions that would require site-specific measures to maintain channel stability or replace disturbed habitat (GeoEngineers 2017d). The crossing of Neil Creek would require typical stream crossing methods because it is rated as a low level of sensitivity. No crossing was rated as having both high risk of project impact potential and high risk of stream and site response potential.

In the range of SONCC coho, Project-typical BMPs would be applied to all streams, while site-specific BMPs would be applied to 19 stream crossings based on their rated category of risk as having sensitive streambed, banks, or riparian revegetation conditions. Stream crossings that are unstable can ultimately adversely affect aquatic resources through loss of local habitat and impacts to downstream habitat from the addition of highly unstable sediment, increasing the recovery time of the specific site to stable conditions.

In addition, substrate characteristics and physical habitat features would be determined through pre-construction surveys, and the upper one foot of existing substrate would be replaced and other physical conditions matched during reconstruction after pipe installation. Clean spawning gravel would be top dressed as appropriate and composition would be based on pebble counts or other appropriate methods on a site-specific basis. PCGP would make some exceptions to this in difficult to access areas, in which case native material comparable to the existing substrate would be used. Many of these actions would be determined prior to construction based on results of the pre-construction survey (see below) and determined by a qualified EI or suitably trained professional who would have the authority to select appropriate site-specific BMP construction methods, bank stability actions, revegetation types, and methods to help reduce the risk of instability of the crossing and potential for future erosion (GeoEngineers 2017d).

A pre-construction survey would be conducted by a technically qualified team on all stream crossings to confirm and clarify conditions developed in the aforementioned matrix analysis. This team would be professionals qualified to assess terrestrial and aquatic habitat and the geotechnical and geomorphic conditions relative to construction across stream channels and ditches. Following these surveys, if significant changes were to occur to parameters of the risk matrix for a crossing, changes would be made to risk level and appropriate final methods of crossing and BMPs applied at each stream crossing. If any crossing is moved into the "high" impact and "high" stream response risk matrix category, a site-specific crossing design would be developed for that site. Project construction would then move forward as described in the permit documents including implementation of special additional BMPs, as described in GeoEngineers (2017d, 2017e, and 2018a), depending on individual site conditions. For waterbodies evaluated as having Low to Moderate Project Impact Potential and Low Site or Stream Response Potential in the Risk Matrix Evaluation (the Blue Management Category, with PCGP Project Typical Construction), BMPs potentially utilized for post-construction site restoration include seeding, planting, and hydromulch or erosion control blankets to minimize surface erosion while new vegetation becomes established, as outlined in the ECRP (see appendix F). Typical site revegetation and backfill will be used to address habitat issues at these sites.

For waterbodies evaluated as having Low to Moderate Project Impact Potential and Moderate Site or Stream Response Potential in the Risk Matrix Evaluation (the Yellow Management Category, having sensitive bed, bank or riparian revegetation conditions selected by the Environmental Inspector or PCGP representative during construction), special, more robust BMPs (in addition to Project Typical BMPs noted in the paragraph above) would include those targeting the streambed component (stratified backfill for high gradient streams, structural fill placement, bank graded/terraced to 3:1, geotextile reinforced slope, fiber rolls) and the streambank component (stream barbs/flow deflectors, toe rock placement, riprap placement, biotechnical "vegetation" riprap, tree revetments). As indicated in GeoEngineers (2017e), typical BMPs were developed for sites in the Yellow management category to address risks posed by bed and bank instability or degradation to existing high quality aquatic habitat. These site-specific BMPs were developed based on field observations of natural analog structures and widely accepted techniques for bank restoration, bed restoration, and aquatic habitat restoration techniques; typical designs of these BMPs are provided in Appendix B to GeoEngineers (2017e).

Waterbodies evaluated as having Low to Moderate Project Impact Potential and High Site or Stream Response Potential in the Risk Matrix Evaluation (the Orange Management Category, having sensitive bed, bank or riparian revegetation conditions selected by qualified professional prior to construction based on site-specific information from pre-construction evaluation) have the highest potential risk for short and long-term channel stability. As described in GeoEngineers (2018a), site-specific restoration plans were developed for crossings that were assessed to be within the Orange management category based on the findings of the preconstruction surveys. The need for site-specific designs is due to more complex geomorphic or hydraulic features that increase risk of channel response to the pipeline or unique, high-value habitat features. Site-specific designs were developed using results of the preconstruction surveys, including geomorphic/hydraulic/habitat observations, topographic cross sections, and profiles collected using a hand level and stadia rod. A written description of site-specific features and restoration priorities, and design drawings are presented for each crossing in Appendix C to GeoEngineers (2017e).

For waterbodies evaluated as having High Project Impact Potential and Low to Moderate Site or Stream Response Potential in the Risk Matrix Evaluation (the Green Management Category, applying Project Typical BMPs with habitat enhancement BMPs) PCGP would use Project Typical Construction BMPs (see above). Channels in this category typically are those that disturb a greater proportion of the existing floodplain or – in narrower streams – potentially disturb more varied aquatic habitat. During site restoration, however, particular effort will be made for opportunistic habitat enhancement BMPs as detailed from observations obtained during the pre-construction survey. These enhancements could include riparian planting to improve existing habitat conditions in the floodplain, placement of large wood or rock to improve in-stream habitat, or modification of existing riprap to improve habitat. A number of the typical BMPs included in Appendix B to GeoEngineers (2018a) were designed to maintain or enhance the aquatic habitat present in the stream. These structures will often act to create complexity in the channel by scouring pools and sorting gravels as well as by providing refugia for juvenile fish. Site-specific restoration plans are provided in Appendix C (GeoEngineers 2018a).

As a follow-up measure to help ensure crossing actions would not adversely affect stream bank and channel structure, PCGP would monitor stream crossings to ensure long-term success of the restoration, maintenance of fish passage, and to identify channel erosion, scour or migration that could destabilize the site or expose the pipeline. As requested by FERC, PCGP developed a monitoring plan (GeoEngineers 2018a) following consultation with representatives from FWS and NMFS (Castro 2015). The monitoring plan would be customized, where necessary, to address risks of stream crossings identified in the Risk Analysis and those identified in subsequent preconstruction surveys.

Monitoring would consist of:

- Annual visits to all stream crossings, regardless of risk level, as part of PCGP's monitoring of pipeline integrity. These visits would be completed by PCGP staff and would note any obvious signs of channel erosion, pipeline exposure, or major shifts in restoration elements. Potential problem areas would be subsequently visited by PCGP and a geoprofessional.
- Aerial reconnaissance would be completed annually for the life of the Pipeline, and stream crossings would be reviewed for major landscape changes such as channel migration and excessive erosion. Potential problem areas would be subsequently visited by PCGP and a geoprofessional.
- Quarterly site visits to all sites in the Orange management category (sites with low-moderate project impact potential and high site or stream response potential, see GeoEngineers 2018a) for 2 years post construction to monitor revegetation success, structural stability of the restoration elements, any changes to fish passage potential resulting from the Pipeline, evidence of channel migration, erosion, head-cutting, or other stream channel movement that could influence stream or pipeline stability. Field measurements would be taken to monitor adjustments to the channel profile and cross-

sectional area.

- Annual site visits to 15 percent of all sites in the Blue management category (sites with low-moderate project impact potential and low site or stream response potential) and 100 percent of all sites in the Yellow management category (sites with low-moderate project impact potential and moderate site or stream response potential, see GeoEngineers 2018a) for 2 years post construction to monitor revegetation success, structural stability of the restoration elements, any changes to fish passage potential resulting from the Pipeline, evidence of channel migration, erosion, head-cutting, or other stream channel movement that could influence stream or pipeline stability. Field measurements would be taken to monitor adjustments to the channel profile and cross-sectional area.
- Annual site visits to 50 percent of the sites in the Yellow and 100 percent of sites in the Orange management category (see GeoEngineers 2018a) by a geo-professional in Years 3, 5, 7, and 10 to monitor revegetation success, structural stability of the restoration elements, any changes to fish passage potential resulting from the project, evidence of channel migration, erosion, head-cutting, or other stream channel movement that could influence stream or pipeline stability. Field measurements would be taken to monitor adjustments to the channel profile and cross-sectional area.
- Observations would be made during all site visits on the effects of cattle/elk browsing on restoration success and of impacts associated with recreational use.
- Revegetation planning along the right-of-way is detailed in the ECRP. The ECRP describes monitoring and performance standards for revegetation.
- Records would be maintained annually to document any significant hydrologic events (flow or rainfall) that occur in between site visits. This shall be done to better understand the site response to moderate or large flood events. As gauging stations are extremely limited over the majority of the crossings along the Pipeline route, rainfall records would be used to identify the potential flooding that may occur in between scheduled monitoring events. These climatic events would be considered during annual monitoring when evaluating site response.
- Unscheduled site visits may be completed at stream crossings on BLM and USFS jurisdiction following localized rainfall events exceeding a 25-year rainfall intensity to monitor revegetation success, structural stability of the restoration elements, any changes to fish passage potential resulting from the Pipeline, evidence of channel migration, erosion, head-cutting, or other stream channel movement that could influence stream or pipeline stability. Field measurements would be taken to monitor adjustments to the channel profile and cross-sectional area.
- Annual reporting in Years 1, 2, 3, 5, 7, and 10 following construction would be provided to outline observations of stream crossings and any remedial action taken to restore site conditions.
- Monitoring frequency and locations may be modified in response to demonstrating site restoration success in the Annual Monitoring reports.

Overall, these actions would reduce potential adverse effects from bank and bed stability to discountable levels to listed coho salmon.

Crossing of Unstable Slopes

Potential impact to waterbodies by deep-seated landslides and shallow, rapidly moving landslide hazards on unchannelized slopes is difficult to evaluate. Slope failure near the waterbody during pipeline operation could result in soil and sedimentation falling into the waterbody. PCGP evaluated all likely unstable areas during selection of the proposed route, and moved the route as necessary to areas considered to have low risk (GeoEngineers 2017k). No surveyed unstable areas have been detected within the route crossing fifth-field watersheds containing the SONCC coho salmon ESU, so adverse effects from slope failure from landslide areas are unlikely.

Aquatic Habitat

There also are potential indirect effects to aquatic habitat from increased suspended sediment from stream crossings. The same approach utilizing TSS concentration and exposure to evaluate levels of risk to fish (Newcombe and Jensen 1996) was applied to quantifying effects of sediment on fish habitat, termed the harmful alteration, disturbance or destruction (HADD) of habitat by Anderson et al. (1996). HADD risk includes concentration and exposure to sediment along with sensitivity of the habitat affected. Most likely, suspended sediment would increase embeddedness of spawning gravels with increasing adverse habitat effects closer to the construction location.

Anderson et al. (1996), adopting the approach of Newcombe and Jensen (1996), used sediment concentration and duration to model the level of adverse effects to fish habitat based on empirical studies.

Anderson et al. (1996) described five severity of ill effect (SE) ranks to habitat:

SE 3: Measured change in habitat preference.
SE 7: Moderate habitat degradation measured by a change in the invertebrate community.
SE 10: Moderately severe habitat degradation as defined by measurable reductions in the productivity of habitat for extended periods (months) or over a large area (kilometers).
SE 12: Severe habitat degradation as measured by long-term (years) alterations in the ability of existing habitats to support fish or invertebrates.
SE 14: Catastrophic or total destruction of habitat in the receiving environment.

The Anderson et al. (1996) HADD model utilizes the same form as the Newcombe and Jensen (1996) models, that is:

$$z = a + b\,(\log_e x) + c\,(\log_e y)$$

where z = SE score, x = duration of exposure in hours, and y = concentration of suspended sediment in mg/l. However, constants a, b, and c in Newcombe and Jensen's Model 1 for juvenile and adult salmonids (a=1.0642, b=0.6068, and c=0.7384) differ in the Anderson et al., (1996) multivariate model for SE to habitat (a=0.032, b=1.008, and c=0.978). As a consequence, for any given duration of exposure (from 2 hours to 6 hours, see table 3.5.3-22), the TSS concentration that would produce a SEV = 3 in the Newcombe and Jensen Model 1 is less than the TSS concentration that would produce a SE = 3 in the Anderson et al. HADD habitat model. Because of nonlinearities in both models, the TSS concentration that would produce a SEV = 7 in the Newcombe and Jensen Model 1 is more than the TSS concentration that would produce a SE = 3 in the Anderson et al., habitat model. The SEV and SE scores are more closely aligned at lower TSS concentrations than at higher concentrations for any given duration of exposure.

Based on the models for suspended sediment concentration and duration of exposure discussed above (see tables 3.5.3-22 and 3.5.3-23), estimates were made for effects to habitat of SONCC coho salmon. Calculated values less than SEV 7 would likely be considered to have little or no substantial effect to functional habitat, while those equal to or greater than SEV 7 likely would be substantial relative to changes in functional habitat conditions for coho salmon. Similar levels of effect due to TSS concentrations and durations of exposure are assumed to apply to coho salmon.

During a failure of dry open-cut construction, TSS concentrations of up to 361 mg/l over background TSS concentrations could last for 6 hours, based on the Newcombe Jensen Model 1 during a wet open-cut (see table 3.5.3-22). If that same concentration is applied in the Andersone et al., HADD model with duration of 6 hours, the SE score is >7 but <8, indicating slightly more damage to habitat than "moderate habitat degradation measured by a change in the invertebrate community." To ensure a SEV score less than 7 for either model, in-stream work to repair a failed containment structure would likely have to be restricted to less than 4 hours. In cases of uninterrupted dry open-cut construction, no substantive adverse effects to coho salmon habitats downstream are expected to occur from sediment generated during stream crossings.

Freshwater Stream Invertebrates

Substrates downstream from in-stream construction sites could be impacted by sediments. Mayflies, caddisflies, and stoneflies prefer large substrate particles in riffles and are adversely affected by fine sediment deposited in interparticulate spaces (Cordone and Kelley 1961; Waters 1995; Harrison et al. 2007). Fish and benthic macroinvertebrate abundance downstream of pipeline construction sites have been reported as short-term reductions following construction-generated suspended sediment (Reid and Anderson 1999). Macroinvertebrate abundance and community composition are highly related to the degree to which substrate particles are embedded by fine material (Birtwell 1999).

Fish emigrate from construction sites and benthic taxa drift downstream to sites where sediment deposition has not affected habitat suitability (Reid and Anderson 1999). In Ontario, stream crossing construction using fluming produced less turbidity and sediment concentrations downstream than construction by wet open cutting streams; wet open cutting resulted in a significant decrease in aquatic invertebrates downstream three days post-construction (Baddaloo 1978 cited in Gartman 1984). One year after construction, there were no significant differences in benthos numbers. Reid et al. (2008) summarized the results of nine wet open-cut pipeline stream crossing studies and noted all measured effects to downstream stream invertebrate population abundance or diversity (six of nine studies) were less than a year in duration with three studies having no measured effects on invertebrate abundace. In general, the percentage of types of stream benthos and invertebrate taxa affected by construction would be in proportion to their abundance during the season of construction, which is likely to be relatively high as crossings would occur during the summer growing season.

Although the discussed studies indicate pipeline construction reduces downstream benthic organism presence, rapid colonization by benthic organisms of disturbed substrate following pipeline construction has been demonstrated elsewhere. In Pennsylvania, samples taken before and 30 days after pipeline construction revealed rapid recolonization of the disturbed and newly-exposed stream substrate by benthic macroinvertebrates (Gartman 1984). Similarly, the number and diversity of aquatic invertebrate taxa in coldwater streams in New York State were unchanged two to four years following pipeline construction from those measured prior to construction (Blais and Simpson 1997). Additionally, most studies of effects on stream invertebrates are based on wet open-cut crossings, which normally have much higher suspended sediment concentrations than the isolated dry stream crossing methods that would be used by the proposed project. Therefore, the overall level of effect of the pipeline crossings on freshwater stream invertebrates, unless crossing sealing failures occur, would be even less than those noted by literature and would not result in substantial reduction in growth or survival of listed coho salmon individuals.

Hydrostatic Testing

Water would be required to hydrostatically test the pipeline. Potential impacts associated with hydrostatic testing include entrainment of fish, transfer of exotic organisms between basins, reduced downstream flows, and impaired downstream uses if test water is withdrawn from surface waters, and erosion, scouring, and a release of chemical additives occur as a result of test water discharge. PCGP would obtain its hydrostatic test water from commercial or municipal sources or surface water rights owners, the sources of which are lakes, impoundments, and streams.

There are four potential locations within the range of SONCC coho ESU where water would be withdrawn for hydrostatic testing and/or dust control. SONCC coho are present in the Rogue River from which an estimated 1,951,591 gallons would be withdrawn from critical habitat. SONCC coho are also present at North Fork Little Butte Creek, which is also critical habitat and from which 2,847,495 gallons would be withdrawn. SONCC coho are assumed to be present in South Fork Little Butte Creek, which drains Fish Lake. An estimated 2,847,495 gallons would be withdrawn from Fish Lake. The fourth water source is the Medford Aqueduct, but no SONCC coho are known or assumed to be present.

There are ten proposed hydrostatic test break sections where test water would be discharged that are within range of SONCC coho ESU. Of the ten, seven hydrostatic test break sections are farther than 0.5 mile from any waterbodies supporting SONCC coho and the other three are farther than 760 feet from coho critical habitat. There would be little to no risk of discharged hydrostatic test water accidentally entering the waterbodies with designated critical habitat.

Discharge volume at each site ranges from about 0.2 to 3.3 million gallons at rates ranging from several hundred to several thousand gallons per minute. Total water used would be about 62 million gallons, with about half from impoundments or lakes, and the rest from streams, including South Umpqua River, Rogue River, North Fork Little Butte Creek, and Klamath River. Within the range of SONCC coho salmon, there are three potential water sources: the Rogue River, North Fork Little Butte Creek, and the impoundment (Fish Lake), and there are 15 potential discharge locations, 14 of which occur within the right-of-way.

PCGP would minimize the potential effects of hydrostatic testing on these watersheds by adhering to the measures in its *Hydrostatic Testing Plan* (see appendix U), including screening intake hoses to prevent the entrainment of fish and other aquatic organisms, meeting NMFS screening criteria, and regulating the rate of withdrawal to avoid adverse impact on aquatic resources or downstream flows. Where test water cannot be returned to its withdrawal source, the water would be treated with a mild chlorine treatment and discharged to an upland location (at least 150 feet from streams with no direct discharge features) through a dewatering structure at a rate to prevent scour and erosion and to promote infiltration. PCGP would obtain all necessary appropriations, withdrawal, and discharge permits through the Oregon Water Resources Department (OWRD). With the implementation of the *Hydrostatic Testing Plan* and BMPs, and obtaining required permits, adequate measures would be in place to prevent direct or indirect effects to SONCC coho salmon that may be in these stream systems.

One of the responsibilities of the EI is to ensure compliance with the requirements of FERC's Upland Plan and Wetland and Waterbody Procedures, and all other environmental permits and approvals, including the multiple plans comprising the POD (see Section 4.0 in the ECRP in appendix F). This would include compliance with the Oregon Department of Water Resources water appropriation permit conditions, which would specify water withdrawal rates and volumes. The EI would ensure that these permit conditions are followed and ensure that water withdrawal pumps used to withdraw surface water would be screened according to NOAA Fisheries screening criteria to prevent entrainment of aquatic species. When pumping water from a source, the pump head would be submerged and maintained on average at the center of the water column so as to prevent sucking in sediments and/or algae lying at the water level surface or sediments resting on the bed of the waterbody. The EI would also ensure that the targeted ramping rate would be managed such that there is no significant decrease of river flows.

Aquatic Nuisance Species

Nonindigenous Aquatic Species (NAS) are aquatic species that degrade aquatic ecosystem function and benefits, in some cases completely altering aquatic systems by displacing native species, degrading water quality, altering trophic dynamics, and restricting beneficial uses (Hanson and Sytsma 2001). Currently, there are 180 reported NAS in Oregon, of which 134 are documented within the USGS hydrologic basins crossed by the proposed Pipeline (USGS 2017).

In the riverine environments crossed by the Pipeline, largemouth and smallmouth bass, introduced as recreational species, prey on juvenile sockeye, coho, and Chinook salmon (Tabor et al. 2007). Management priorities in Oregon concentrate on the NAS whose current or potential impacts on native species and habitats, and economic and recreational activity in Oregon, are known to be significant (Hanson and Sytsma 2001). Some of the major potential freshwater invasive species are mussels, including the zebra and quagga mussels (*Dreissena polymorpha*, and *Dreissena rostriformis bugenisis*), as well as Chytrid fungus and other species of concern.

Aquatic nuisance species could potentially be introduced into Pipeline project area waters by basin transfer through hydrostatic testing or be carried on equipment that is moved from outside of the region or between basins. PCGP has developed BMPs and guidelines to avoid the potential spread of the aquatic nuisance species and pathogens of concern (see *Hydrostatic Testing Plan*, appendix U) in consultation with the BLM and Forest Service as well as the Center for Lakes and Reservoirs and Aquatic. If determined to be feasible for hydrostatic testing requirements, all water used in hydrostatic testing would be returned to its withdrawal source location after use; however, cascading water from one test section to another to minimize water withdrawal requirements may make it impractical to release water within the same watershed where the water was withdrawn. If it is not possible to return the water to the same water basin from where it was withdrawn, PCGP would employ an effective and practical water treatment method (chlorination, filtration, or other appropriate method) to disinfect the water that would be transferred across water basin boundaries. The hydrostatic test water would be treated after it is withdrawn and prior to hydrostatic testing.

PCGP would implement a three-step BMP treatment process to prevent the potential spread of invasive species and forest pathogens from non-municipal surface water sources used during hydrostatic testing. The hydrostatic test water treatment process would incorporate screening/filtration during water withdrawal, chlorine treatment, and upland discharge at least 150 feet from wetlands or waterbodies with no direct discharge to these features. All hydrostatic test water would be released through a dewatering device such as a straw bale structure or sediment bag, in a manner to promote infiltration. Further, all hydrostatic release locations would be monitored after construction to ensure noxious weeds have not become established.

As explained in the Hydrostatic Test Plan (see appendix U), PCGP proposes to use a treatment of 2 ppm or 2 mg/L of free chlorine residual with a detention time of 30 minutes to treat all non-municipal surface waters that would be used as a water source for hydrostatic testing purposes. Chlorinated water would be released according to ODEQ criteria to prevent water quality impacts, potential effects to aquatic species, and to minimize potential impacts to sensitive areas.

Fuel and Chemical Spills

Fisheries habitats could be adversely affected if petroleum products were accidentally discharged into aquatic environments. Such materials are toxic to algae, invertebrates and fish. Of the products likely to be present during construction, data compiled from a wide range of sources indicate that diesel fuels and lubricating oils are considerably more toxic to aquatic organisms than other, more volatile products (gasoline) or heavier crude oil (Markarian et al. 1994). Release of diesel fuel in freshwater habitats significantly reduced aquatic invertebrate densities and species richness at least 3 miles downstream, but invertebrate densities recovered within a year (Lytle and Peckarsky 2001). Impacts to aquatic habitats that primarily affect aquatic substrates – spawning, incubating and rearing habitats – can remain for much longer periods (Markarian et al. 1994).

Equipment used for construction across waterbodies could potentially release hydraulic fluid comprised of a variety of compounds, the most common of which are mineral oil-based, organophosphate esters, and polyalphaolefins (HHS 1997). Release from machinery can occur through faulty seals, hoses, sumps and reservoirs, or general system failure. Components of mineral oil and polyalpaolefins do appear to bioaccumulate in animals whereas larger molecular constituents in organophosphate esters can concentrate in fish, primarily partitioning in fat tissue (HHS 1997). In general, toxicity of organophosphate esters is greater than either mineral oil or polyalphaolefin-based hydraulic fluids when inhaled, ingested, and in contact with the skin for humans. Toxicities have not been clearly described for aquatic invertebrates or fish and would be dependent on specific chemical components (HHS 1997).

Inadvertent spills of fluids used during construction, such as fuels and lubricants, could contaminate wetland soils and vegetation if not sufficiently contained. To minimize the potential for spills and any impacts from such spills, PCGP's SPCC Plan (see appendix L) would be implemented. In general, hazardous materials, chemicals, fuels, and lubricating oils would be not be stored, nor would refueling operations or concrete-coating activities be conducted within 100 feet (150 feet on BLM and NFS lands) of a wetland or waterbody in accordance with FERC's *Procedures* (see appendix C) and the SPCC Plan (see appendix L), except where no reasonable location is possible and additional containment steps have been taken. The SPCC Plan would be updated with site-specific information prior to construction. Adherence to these plans and procedures would results in effects to the SONCC ESU coho salmon that would be discountable.

Streambed Scour

Fluvial erosion represents a potential hazard to the Pipeline where streams are capable of exposing the pipe as a result of channel migration, avulsion, widening, and/or streambed scour. The principal hazard resulting from channel migration and streambed scour is complete or partial exposure of the Pipeline within the channel from streambed and bank erosion or within the floodplain from channel migration and/or avulsion. To address this potential hazard, PCGP completed a channel migration and scour analysis (GeoEngineers 2017i and GeoEngineers 2018b). In this analysis, stream crossings along the route were evaluated with respect to potential future risk to the Pipeline that could result from channel bed scour and/or lateral migration. The evaluation was conducted in two phases: Phase I involved a desk top evaluation and small field investigation in which all stream crossings were ranked for potential risk; Phase II involved detailed field investigation and analyses of those stream crossings that were concluded to pose risk to the Pipeline based on the Phase I study.

Minimizing the effects of migration and scour hazards to the Pipeline can be accomplished with the following (GeoEngineers 2017i and GeoEngineers 2018b):

- At each channel crossing, bury the pipe below the estimated depth of streambed scour. Where bedrock is encountered at shallower depths than the estimated scour depth, the elevation of competent bedrock represents the limit of scour.
- Where feasible, place the pipe into bedrock.
- Within floodplains adjacent to migrating channels, bury the pipe below the projected depth of the channel thalweg within the 50-year channel migration zone.

The Pipeline will be designed to protect the integrity of the pipe, which may include increasing the depth of cover to more than the 5-foot minimum to accommodate the potential for long-term scour and bank stabilization. At a minimum, PCGP will design all waterbody crossings to meet U.S. Department of Transportation standards (CFR 49 Part 192). Additional depth will be evaluated and considered based on GeoEngineers' (2018b) Channel Migration and Scour Analysis or other site-specific investigations, considering the final route alignment. From the results of the Channel Migration and Scour Analysis (GeoEngineers 2018b), PCGP would bury the pipe below the estimated 100-year scour depth or into competent bedrock, whichever is shallower.

Effects to Hyporheic Exchange

The hyporheic zone is defined by the extent of surface-subsurface mixing, the hyporheic exchange that moves surface water into the surrounding alluvium and back to the river again through the porous sediment surrounding a river (Tonina and Buffington 2009). The downwelling flows of surface water supply the wetted hyporheic zone with dissolved oxygen, which sustains organisms in the aerobic environment but decomposition of organic materials in the hyporheic zone may deplete oxygen concentrations in return flows to the surface (Findlay et al. 1993; Tonina and Buffington 2009). Alternatively, nutrient enrichment to surface waters occurs with hyporheic exchange by upwelling flows (Valett et al. 1990). For example, hyporheic flow is important for surface water/groundwater interactions that influence bull trout spawning sites and use of other habitats (e.g., juvenile rearing, migration) (FWS 2005h) and presumably those of other salmonids.

GeoEngineers (2017j) developed a ranking procedure to qualitatively evaluate site conditions at waterbody crossings and the probable influence on hyporheic flow and whether a stream channel will have an active and functional hyporheic zone. The procedure assigns a value of 1 to 5 for different criteria: alluvial vs. bedrock substrate, substrate sediment size, stream flow period, presence of an upstream drainage basin, and channel gradient vs. percent drainage area contribution to the 5th field HUC upstream from the pipeline crossing. The procedure includes weighting factors emphasizing importance of some criteria over the others. In the range of SONCC coho, there was a total of 62 stream crossing evaluated in the four 5th field watersheds affected in the Upper Rogue Subbasin. Of those, four crossings (1 in Big Butte Creek and 3 in Little Butte Creek watersheds) were evaluated as having high sensitivities to hyporheic zone alterations while 20 crossings (2 in Trail Creek, 1 in Rogue River-Shady Cove, 2 in Big Butte Creek, and 15 in Little Butte Creek watersheds) had moderate sensitivities. The remaining 38 crossings scored low sensitivity to hyporheic zone alterations.

Construction of the pipeline using dry open cut construction would require removal of native stream bed and bank material from the stream. The subsequent burial of the pipeline would involve replacing those native materials back in the streambed and stream banks. At crossings with steep natural stream banks (e.g., slopes steeper than 3H:1V [horizontal to vertical]), additional stabilization measures such as compaction of backfill may be required that could locally alter stream bank permeability from pre-construction conditions. Removal and replacement of native stream material has the potential to locally disrupt the structure and organization of the hyporheic zone in the immediate area of the pipeline crossing. However, such alterations are expected to be minimal relative to adjacent unaffected streambed and stream banks and could either increase or decrease permeability over an extremely narrow segment of a stream channel, up to 12 feet in width at the maximum trench width. Local disruption of hyporheic function by construction and presence of the pipeline would not be expected to result in measureable effects to dissolved oxygen and/or nutrient enrichment and would not adversely affect coho.

BMPs that reduce the potential impacts to the hyporheic zone include the following:

- Native material that is removed from the pipeline trench during excavation across stream channels will be used to backfill once the pipe is in place in order to minimize potential changes to preconstruction permeability.
- Trench plugs will be installed at the base of slopes adjacent to wetlands and waterbodies and where needed to avoid draining of wetlands or affecting the original wetland or waterbody hydrology.

While the potential impact of pipeline construction on hyporheic exchange is considered to be low at all stream crossings considering the proposed construction methods, PCGP proposes these additional measures to further reduce the potential for even localized impacts to water quality from hyporheic exchange at the stream crossings identified as having high hyporheic sensitivity (Appendix A to GeoEngineers 2017j):

- Document streambed stratigraphy prior to construction if possible, or if not possible, during construction to aid in site restoration. Such documentation will be conducted by staff trained in recognizing and observing river channel processes. If done during construction, this may be performed by the EI after receiving suitable training.
- Segregate active streambed gravels and cobbles from underlying streambed materials (including fractured bedrock) to their natural depth and replace gravels/cobbles to this natural pre-construction depth.
- Below active stream gravels, replace native material in a manner to match upstream and downstream stratigraphy and permeability to the maximum extent practicable.

Runoff from Permanent, Temporary, Existing Access Roads (PARs, TARs, EARs), and TEWAs

Run-off from PARs, TARs, EARs, and TEWAs can result in sediment delivery affecting stream supporting SONCC coho. PCGP proposes to construct three new TARs and four new PARs within the range of SONCC coho (table 3.5.3-26). Potential for sediment delivery to streams following construction of the roads was evaluated by applying sediment and drainage assessment components of the Washington Road Surface Erosion Model or WARSEM (Dube et al. 2004) which has been previously applied in Oregon (Surfleet et al. 2011). Specific individual WARSEM modelling components have been used to evaluate levels of risk for delivery of sediment to streams nearest each TAR and PAR as well as nearest streams supporting ESA-species. Two TARs have low risks of sediment delivery to any stream but only one TAR has a low risk of delivery to an ESA stream – North Fork Little Butte Creek which supports SONCC coho with designated critical habitat. None of the other proposed TARs and PARs have any risk of sediment delivery to streams closest to new road sites.

Similar risk analyses were conducted for portions of EARs that are known to occur within 1SPTH of streams with designated critical habitat for coho and other streams known or assumed to provide habitat for coho in the two ESUs. Finally, TEWAs that are proposed within 1SPTH of critical habitat for coho were evaluated for risks of sediment delivery to coho critical habitat. BMPs proposed by PCGP that would be applied to PARs, TARs, EARs, and TEWAs to prevent sediment delivery in coho critical habitats and other coho-bearing streams are summarized from the Erosion Control and Revegetation Plan (ECRP – appendix F to the APDBA).

The risk analysis utilizes four modelling components required for sediment and drainage assessment as applied in WARSEM. The components that were evaluated for each TAR/PAR include:

- Dominant lithology – information source: Oregon Department of Geology and Mineral Industries, Oregon Geologic Data Compilation 6 (OGDC-6 geodatabase) available from http://www.oregongeology.org/sub/ogdc/index.htm. Dominant lithology coinciding with locations of each PAR or TAR was evaluated at each location.
- Road gradient – evaluated gradient at each PAR or TAR on topographic map using contour lines (rise divided by run) if road gradient >5 percent grade. If less than 5 percent, gradient was noted as 0 – 5%.
- Annual rainfall – information source: Western Regional Climate Center, Western U.S. Climate Historical Summaries available from https://wrcc.dri.edu/Climsum.html. Annual

rainfal at each location was evaluated by adjusting the average total precipitation for snowfall during the period of record for National Weather Station closest to each PAR or TAR.

- Delivery – evaluated closest distance of each PAR or TAR to any stream segment (perennial or intermittent, using National Hydrography Dataset, available at https://nhd.usgs.gov/data.html) and to each stream segment supporting ESA-listed fish using ODFW Oregon Fish Habitat Distribution Data available at https://nrimp.dfw.state.or.us/nrimp/default.aspx?pn=fishdistdata. In addition, distances of nonforested and forested vegetation intervening between road and stream segment were measured using GIS.

Technical documentation (Appendix A) in Dube et al. (2004) was used to evaluate levels of risk for erosion and sediment delivery contributed by each of these four site-specific components at each proposed PAR or TAR.

In addition to site-specific conditions, PCGP has specified road lengths and widths for each proposed PAR or TAR. Although road surfacing has not been specified, PCGP has proposed surfacing enhancements as necessary in Section 2.3 of the Transportation Management Plan (see POD). Road length, width, and surfacing are required components for use in WARSEM as well as daily average traffic volume, which is currently unknown but may be hypothesized using categorical traffic levels in technical documentation for WARSEM (Appendix A, in Dube et al. 2004) and a road age factor which is irrelevant to the evaluation of risk for sediment production since none of the proposed roads have been constructed.

The following components required for WARSEM cannot be evaluated for the PARs and TARs: and were not included in this risk analysis:

- Road prism geometry
- Cuttslope height
- Cuttslope cover
- Drainage ditch width
- Drainage ditch condition

WARSEM estimates the average annual amount of road surface erosion that is delivered to a stream from each road segment modeled by using calculations based on empirical relationships derived from road erosion research (Dube et al. 2004). The model uses the following formulas to calculate road surface erosion and sediment delivery to a stream:

Total Sediment Delivered to a Stream from each Road Segment (in tons/year) = (Tread & Ditch Sediment + Cutslope Sediment) x Road Age Factor

Tread & Ditch = Geologic Erosion Factor x Tread Surfacing Factor x Traffic Factor x Segment Length x Road (Tread + Ditch) Width x Road Gradient Factor x Rainfall Factor x Delivery Factor

Cutslope = Geologic Erosion Factor x Cutslope Cover Factor x Segment Length x Cutslope Height x Rainfall Factor x Delivery Factor

New TARs and PARs. Some of the relevant information used to derive various "Factors" necessary for WARSEM are provided in the tables, below. Percent gradient at locations of proposed TARs and PARs and the associated Road Slope Factor is provided in table 3.5.3-26. The gradient of a road segment influences the erosion rate. Three Road Slope Factors are used in WARSEM and apply to gradients estimated in table 3.5.3-26. The steepest gradient estimated for any proposed road was 9% for TAR-143.19 which corresponds to a Road Slope Factor of 1.0. Except for that road and TAR-141.10, the other the proposed road locations are on relatively flat terrain with gradients estimated from 0 to 5% and Road Slope Factors of 0.2.

TABLE 3.5.3-26

Location and Physical Characteristics for Proposed TARs and PARs in Range of SONCC Coho.

Road Identification	Fifth Field Watershed	Latitude	Longitude	Length (feet)	Width (feet)	Surface Area (acres)	Gradient (Road Slope Factor) a/
TAR-141.10	Little Butte Creek	42°29'6.129 N	122°36'41.25"W	471	25	0.44	7% (1.0)
TAR 143.19	Little Butte Creek	42°27'30.095"N	122°36'14.968"W	146	20	0.07	9% (1.0)
TAR 145.60	Little Butte Creek	42°25'36.74"N	122°35'31.543"W	391	20	0.18	0 to 5% (0.2)
PAR-113.66	Trail Creek	122°53'7.115"W	42°44'43.236"N	73	25	0.04	0 to 5% (0.2)
PAR-122.18	Shady Cove-Rogue River	122°49'4.483"W	42°38'43.179"N	181	25	0.10	0 to 5% (0.2)
PAR-132.46	Big Butte Creek	122°40'51.653"W	42°34'38.274"N	271	25	0.16	0 to 5% (0.2)
PAR-150.70	Little Butte Creek	122°32'20.863"W	42°22'58.585"N	282	25	0.16	0 to 5% (0.2)

a/ Road Slope Factors: 0.2 for gradients of <5%; 1.0 for gradients of 5-10%; 2.5 for gradients >10%. See Table A-6, Appendix A, Dube et al. 2004

Erodibility of a road segment is related to soil characteristics at the site location which are related to the parent lithology and weathering. Relative erodibility for different rock types of different geologic ages that are associated with proposed TARs and PARs are provided in table 3.5.3-27 as the Geologic Erosion Factor corresponding to each lithology. The highest Geologic Erosion Factor (5) is associated with Quaternary and Tertiary volcanic ash and tuff as well as with weathered granite and other intrusive rocks. Deeply weathered sedimentary rocks that degrade to silt and sand also have the highest Geologic Erosion Factor. Weathered schist or gneiss from the Tertiary and older formations have moderate Geologic Erosion Factor (2), and others in table 3.5.3-27 have low Geologic Erosion Factor (1).

Rainfall strongly influences erosion and sediment transport. Instead of using the PRISM climatic model as applied applied in WARSEM), data from NWS cooperating stations closest to each proposed TAR and PAR were used to evaluate average annual rainfall (average monthly precipitation adjusted for average monthly snowfall, described in Equation 6, Appendix A, Dube et al. 2004) for each station's period of record. That information is provided in table 3.5.3-27. A Rainfall Factor, derived from the average annual rainfall at the closest NWS station, is computed from Equation 7, Appendix A, Dube et al. (2004) and provided in table 3.5.3-27. In general, average annual rainfall and Rainfall Factors for proposed TARs and PARs decline with distance along the Pipeline route from west to east.

TABLE 3.5.3-27

Surface Lithology and Average Annual Total Rainfall Estimated at the National Weather Service Station (NWS) Closest to Each Proposed TAR and PAR in Range of SONCC Coho.

Road Identification	Dominant Lithology a/	Geologic Erosion Factor b/	Closest NWS Station (NWS Number) c/	Period of Record	Station Distance to Road (miles)	Average Annual Rainfall d/ (inches)	Rainfall Factor e/
TAR-141.10	Oligocene/Miocene basaltic andesite	low (1)	Lake Creek 5 SE (354534)	1955-2009	8.7	23.84	1.9
TAR 143.19	Oligocene/Miocene basaltic andesite	low (1)	Lake Creek 5 SE (354534)	1955-2009	6.9	23.84	1.9
TAR 145.60	Oligocene/Miocene basaltic andesite	low (1)	Lake Creek 5 SE (354534)	1955-2009	5.0	23.84	1.9
PAR-113.66	Eocenet tuff volcaniclastic rocks	high (5)	Trail 12 NE (358588)	1951-1970	11.2	41.03	4.2
PAR-122.18	Eocene intermediate and silicic ash flow tuff	high (5)	Lost Creek Dam (355055)	1970-2016	6.8	32.98	3.0
PAR-132.46	Oligocene/Miocene basalt, basaltic andesite and andesite	low (1)	Lost Creek Dam (355055)	1970-2016	6.2	32.98	3.0
PAR-150.70	Miocene basaltic andesite	low (1)	Lake Creek (354634)	1955-2009	1.2	23.84	1.9

b/ Geologic Erosion Factor surmised from Figure A-1 and Table A-1 in Appendix A, Dube et al. 2004.
c/ Closest NWS Station (with Cooperator Number) based on coordinates provided in individual station data, available from Western Regional Climate Center, Western U.S. Climate Historical Summaries (available from https://wrcc.dri.edu/Climsum.html).
d/ Average Annual Rainfall derived from average monthly precipitation adjusted for average monthly snowfall, described in Equation 6, Appendix A, Dube et al. (2004).
e/ Rainfall Factor derived from the average annual rainfall at the closest NWS station, computed using Equation 7, Appendix A, Dube et al. (2004).

The Delivery Factor is a key component of WARSEM and subsequent estimation of risks by erosion and road-generated sediments to aquatic resources. Sediment transport is dependent on the slope of the hillside, infiltration capacity of the soils, volume and depth of runoff water, and obstructions on the hillside (e.g., effectiveness of vegetative buffers at trapping sediment) that would slow runoff water and trap the sediment (Dube et al. 2004). While roads farther than 200 feet from a stream are assumed not to deliver sediment to streams unless a gully exists that allows for transport of sediment from the road to the stream, roads within 100 to 200 feet of a stream are assumed to allow for delivery of 10 percent of produced sediment; roads <100 feet from a stream allow for delivery of 35 percent of produced sediment, and drainage from a road to a stream allows for 100 percent of produced sediment (see Table A-10, Appendix A, Dube et al. 2004).

This simplified scheme identifies four levels for the Road Delivery Factor in WARSEM: 0, 10, 35, and 100 (see table 3.5.3-28). Although vegetation characteristics are not factors in WARSEM, distances through nonforested and forested vegetation that intervene between each proposed road and the closest stream (and closest stream supporting ESA species) are included in table 3.5.3-28. The highest Road Delivery Factor in table 3.5.3-28 is 35 (indicating delivery of 35 percent of sediment produced by the new road) for PAR-122.18 which is 36 feet from Cricket Creek, a waterbody that does not support SONCC coho at the road location but is assumed to support SONCC coho 1,385 feet downstream from the road. TAR-145.60 is 111 feet from North Fork Little Butte Creek which provides critical habitat for SONCC coho but the Road Delivery Factor is 10, indicating delivery of 10 percent of sediment produced by the new PAR.

TABLE 3.5.3-28

Estimated Risks for Sediment Delivery to Any Closest Stream and Closest Stream with ESA Species from Each Proposed TAR and PAR in Range of SONCC Coho with Distances of Vegetation Intervening between Road and Stream

Road Identification	Closest Stream (distance)	Flow a/	Intervening Vegetation (distance)	Road Delivery Factor b/	Closest ESA Stream (distance)	Intervening Vegetation (distance)	Road Delivery Factor b/

The products of three site-specific erodibility factors - Road Slope, Rainfall, and Geologic Erosion factors – are provided in table 3.5.3-31. The product of the three factors is assumed to represent a level of risk for erosion from each road's surface and has been ranked as Low (product <1), Moderate (product from 1 to 5), and High (product >5). The largest three factor product is 4.2 for PAR-113.66 due to a high Rainfall Factor and relatively high Geologic Erosion Factor. Table 3.5.3-29 also includes the Road Delivery Factor for any stream closest to each proposed road. The four factor products (including the three Site Erodibility Factors and Road Delivery factor for any closest stream) have been ranked as None (product of 0), Low (product >0 to 20), Moderate (product >20 to 50), and High (product >50).

The risk analysis indicates PAR-122.18 has a high risk of sediment delivery to any stream located near it but, because of distance, poses no risk to a stream with listed fish or designated habitat. TAR-145.60 has a low risk of sediment delivery to an ESA stream, to the North Fork Little Butte (nearest stream), which is designated critical habitat for SONCC coho. None of the other new TARs and PARs in table 3.5.3-29 pose any risk for sediment delivery to any stream.

TABLE 3.5.3-29

c/ Road Delivery Factor from table 3.5.3-28.

EARs. A similar analysis was conducted for EARs that could potentially be utilized during project construction, accessing the construction right-of-way and other project components. The following analysis is limited to segments of EARs that are within 1SPTH from streams within range SONCC coho, including designated critical habitats. EARs include federally-managed roads located on federally-managed lands and privately-owned lands that will be used/authorized during timber removal, construction, and operations to access the construction and operational right-of-way.

There are 65 EARs totaling 3.66 miles within 1SPTH of waterbodies within range of SONCC coho. Of those, 14 are paved, 13 are graveled, and 38 have dirt surfaces. Three EARs with dirt surfaces and two with gravel survaces are within 1SPTH of waterbodies with critical habitat for SONCC coho and included in table 3.5.3-30. Risk estimates for sediment delivery from each of those EARs to four streams with critical habitat in range of SONCC Coho are summarized in table 3.5.3-30 utilizing the same data sets and factors (Road Slope Facto, Rainfall Factor, Geologic Erosion Factor, and Road Delivery Factor) described above for streams closest to new proposed TARs and PARs. In addition, the Road Surface Factor (1 for dirt, 0.5 for gravel) is included in a Five Factor Product is assumed to represent a level of risk for erosion from each road's surface and has been ranked as Low (product <10), Moderate (product from 10 to <100), and High (product >100) in table 3.5.3-30.

The largest five factor product in table 3.5.3-30 is 225 for the EAR within 1SPTH of Canyon Creek due to its dirt surface, relatively high Rainfall and Geologic Erosion factors, and direct delivery of sediment assumed since the road crosses Canyon Creek. The EAR within 1SPTH of Salt Creek also crosses the waterbody but five factor product is 28 with a moderate risk due to a lower Rainfall Factor and lower Geologic Erosion Factor due to Oligocene/Miocene basaltic andesite lithology even though the EAR has a dirt surface.

TABLE 3.5.3-30

Summary of New Road Erosion Risks and Risks of Sediment Delivery to
Streams with Coho Critical Habitat by Existing Dirt and Gravel Surfaced Roads within 1 SPTH in Range of SONCC Coho

Watershed and Critical Habitat with EAR	Number of EARs	Road Surface	Total Road Length (miles)	Road Surface Factor a/	Road Slope Factor b/	Rainfall Factor c/	Geologic Erosion Factor d/	Road Delivery Factor e/	Five Factor Product	Risk of Sediment Delivery to Critical Habitat
Trail Creek										
Canyon Creek	2	Dirt	0.15	1	0.2	2.2	5	100	225	High
Shady Cove-Rogue River										
Rogue River	1	Gravel	0.01	0.5	0.2	2.2	5	10	11	Moderate
Little Butte Creek										
Salt Creek	1	Dirt	0.12	1	0.2	1.4	1	100	28	Moderate

North Fork Little Butte Creek	1	Gravel	0.03	0.5	0.2	1.4	1	35	5	Low

a/ Road Surface Factors: 0.5 for gravel, 1.0 for dirt. See Table A-3, Appendix A, Dube et al. 2004
b/ Road Slope Factors: 0.2 for gradients of <5%; 1.0 for gradients of 5-10%; 2.5 for gradients >10%. See Table A-6, Appendix A, Dube et al. 2004
c/ Rainfall Factor derived from the average annual rainfall at the closest NWS station, computed using Equation 7, Appendix A, Dube et al. 2004.
d/ Geologic Erosion Factor surmised from Figure A-1 and Table A-1 in Appendix A, Dube et al. 2004 based on Dominant Lithology evaluated from Oregon Department of Geology and Mineral Industries, Oregon Geologic Data Compilation 6. Available from http://www.oregongeology.org/sub/ogdc/index.htm.
e/ Road Delivery Factor: Distance from stream, >200 feet = 0, 100 to 200 feet = 10, <100 feet = 35, and direct delivery = 100. See Table A-10, Appendix A, Dube et al. 2004.

TEWAs. Construction will primarily use a 95-foot wide construction right-of-way corridor and associated TEWAs. However, in specified areas such as wetlands, sensitive visual areas and residential areas, the construction right-of-way will be reduced to 75 feet wide to minimize disturbance. In most cases, except where topographical constraints occur, TEWAs have been located at least 50 feet away from wetland boundaries to minimize potential impacts to wetland buffers and riparian areas. Where TEWAs are located closer than 50 feet from a waterbody and the adjacent upland does not support cultivated or rotated cropland or other disturbed land, a modification from FERC's Wetland and Waterbody Procedures (Section V.B.2.a. & b.) has been requested.

Distances of TEWAs to Waterbodies within 1 SPTH of designated critical habitat for SONCC Coho were measured using GIS and digitized waterbody streambanks and TEWA polygons. Consequently, distances could change once boundaries of TEWAs are surveyed on the ground. From these estimates, there are there are seven waterbodies with a total of 21 TEWAs within 1SPTH of critical habitat for SONCC coho, totaling 3.96 acres.

Risk estimates for sediment delivery from each of TEWAs similar to that described above for TARs, PARS, and EARs were not conducted since the procedures in WARSEM modeling is not applicable to TEWAs except for the road delivery factor (distance from a TEWA to a stream). All TEWAs in table 3.5.3-31 that are within 1 SPTH of waterbodies with designated critical habitat are closer than 200 feet to streams, two TEWAs are less than 200 feet but >100 feet to streams, and 19 TEWAs within 1SPTH of waterbodies with designated critical habitat are <100 feet from the streams; 12 TEWAs are within 50 feet of designated critical habitat and sediment delivery to critical habitat has the greatest potential from those 12 TEWAs and a portion of TEWA 128.55-N overlaps critical habitat, potentially capbable of direct sediment delivery based on the sediment delivery distance categories in WARSEM (Table A-10, Appendix A, Dube et al. 2004).

TABLE 3.5.3-31

Individual TEWAs within One Site-Potential Tree Height of Streams with Critical Habitats in Watersheds within Range of SONCC Coho

Erosion of new road surfaces, existing road surfaces, and exposed surfaces of TEWAs within 1 SPTH have the potential for sediment delivery to streams and could lead to adverse effects on fish and fresh water benthic invertebrates similar to those described above. As discussed in Section 2.3 of PCGP's Transportation Management Plan (see POD), PCGP will perform road surfacing structural capacity assessments and place additional road surfacing (aggregate or bituminous as appropriate) as needed for the planned use to minimize the potential for both road-related and off-road resource damage. In WARSEM modeling, the Road Tread Surfacing Factor is 1 for roads with native materials surface but is 0.2 for a gravel (aggregate) surface and 0.03 for an asphalt (bituminous) surface. Application of surfacing materials to any of the new TARs and PARs in table 3.5.3-29 with low to high risks of sediment delivery to streams would decrease levels of erosion and quantities of sediment delivered. Surfaces of all new PARs would be graveled thereby decreasing their erosion potential. Further, PARs and TARs would meet land-managing agencies' engineering design and road management standards consistent with the intended use of the road and all applicable agency BMPs; all applicable agency BMPs for erosion control will be implemented. In addition, PCGP will install appropriate erosion and sediment control BMPs along the access roads as determined necessary by PCGP's EI in cooperation with applicable agency officials. All land-managing agency roads are subject to short-term traffic restrictions and/or closures due to seasonal or unusual weather conditions, user safety or when necessary to prevent facility or resource damage.

PCGP's ECRP also identifies mitigation measures that may be required to minimize potential impacts to existing culverts prior to access road use, to allow safe construction equipment travel and prevent damage to the culverts. PCGP has completed an assessment to identify where proposed road improvements or where new permanent or temporary access roads would cross waterbodies and culvert installations would be required. The assessment used PCGP's wetland survey data where access was available. Where access was not available, the assessment used

FWS' National Wetland Inventory (NWI) data[5], USGS National Hydrography Dataset (NHD) data[6], ODF statewide streams data[7], LiDAR data, and aerial photography to interpret waterbody crossings. Identified waterbody crossings were also correlated with PCGP's preliminary access road improvement plans that were completed to evaluate improvements necessary to accommodate trucks hauling pipe (Dyer Partnership 2015). The access road improvement plans (Dyer Partnership 2015) were based on field investigations and identified locations where new culverts or culvert extensions would be necessary.

The new culverts needed to cross waterbodies are located on small intermittent headwater streams where there is no fish presence. The measures outlined in PCGP's Culvert Crossing Best Management Practices (see attachment F to the ECRP in appendix F of the POD) and appropriate erosion control and revegetation measures outlined in the ECRP would be implemented during any road improvement activities. As indicated in the Culvert Crossing BMP, prior to construction, existing culverts will be investigated along all private roads and federally authorized roads (i.e., BLM and Forest Service) identified for access to the construction right-of-way. These investigations would occur on access roads where PCGP is authorized to be and/or where PCGP has negotiated an access use agreement or easement. The investigation will determine the condition and integrity of existing culverts and identify any location that may require mitigative measures to ensure construction activities do not damage or impair the existing function of the culverts. Mitigative measures may be required prior to access road use to allow safe construction equipment travel and prevent damage to the culverts. In select locations, replacement and/or modification of a culvert may be necessary. As noted above, PCGP has completed an assessment to identify where proposed road improvements would cross waterbodies and culvert installations would be required. The new culverts identified are located on small intermittent headwater streams where there is no fish presence.

The ECRP also describes the application of sediment barriers, temporary slope breakers, mulch, dust control, and permanent erosion control measures that will further minimize sediment discharges from a site after construction is complete. In forested areas, during timber clearing/right-of-way grading operations slash-filter windrows may be constructed on the downhill edge of the construction right-of-way and TEWAs, as directed by the EI. Slash-filter windrows will be constructed of logging slash, including cull logs, tree tops, limbs, and branches laid parallel to the right-of-way to effectively filter sediment, reduce runoff velocities, and prevent stream sedimentation. Sediment barriers would generally be placed as follows:

- at the base of slopes adjacent to road, wetland and waterbody crossings where sediment could flow from the construction right-of-way onto the road surface or into the wetland or waterbody;adjacent to wetland and waterbody crossings, as necessary,
- to prevent sediment flow in the wetland consistent with the requirements of FERC's Wetland and Waterbody Procedures; and
- on the down slope side of the right-of-way where it traverses steep side slopes.

[5] https://www.fws.gov/wetlands/nwi/overview.html
[6] https://nhd.usgs.gov/data.html
[7] http://www.oregon.gov/ODF/AboutODF/Pages/MapsData.aspx

The EI will inspect temporary erosion control structures at least on a daily basis in areas of active construction and equipment operation. In areas where active construction and equipment operation are not occurring, inspections will be made at least weekly. All structures will be inspected by the EI within 24 hours of 0.5 inch or greater of rainfall. The EI will be responsible for ensuring that ineffective temporary erosion control measures are repaired as soon as possible but no more than 24 hours after discovery, unless prohibited by exigent circumstances in which case repair will be effectuated as soon as possible. Whenever possible, the EI will inspect erosion control measures in advance of predicted storm events and take preventative measures to minimize the potential for off right-of-way sedimentation.

Temporary sediment barriers will be maintained in place until permanent revegetation measures are determined successful or until the upland areas adjacent to wetlands, waterbodies or roads are stabilized. The structures will be removed once the area has been successfully restored.

Mulch (certified weed free) will be applied if construction and restoration activities are interrupted for extended periods, such as when seeding cannot be completed due to seeding period restrictions. In these areas mulch will be applied uniformly over the area to cover the ground surface at a rate of two tons/acre of straw or hay or its equivalent. In addition, the mulch application rate will also be increased to 3 tons/acre on all slopes within 100 feet of waterbodies and wetlands. The mulch will consist of certified weed-free straw or wood fiber hydromulch. On federal lands, in the event that construction activities are extended beyond the dry season (i.e., May 1 to October 31), soil disturbance in excess of 0.5 acre will have effective ground cover provided or other effective BMPs will be utilized as discussed in the ECRP to prevent sedimentation beyond the approved construction right-of-way and associated TEWAs or into wetlands and waterbodies.

These provisions from the Transportation Management Plan and ECRP are consistent with BMPs identified in Appendix C to Dube et al. (2004) and will ensure that potential sediment delivery from the PARs and TARs is eliminated or minimized resulting in minimal effects to fish and freshwater benthic invertebrates.

Runoff from Facility Surfaces

There are three contractor and pipe storage yards, four rock source and disposal sites, three new temporary access roads, two new permanent access roads, and four aboveground facilities within the range of SONCC coho. One yard, Rogue Aggregates in the Gold Hill-Rogue River Watershed, is within 100 feet of the Rogue River. None of the rock source and disposal sites are near waterbodies inhabited by SONCC coho and no new PARs are near coho habitat. .

Stored materials at the yards may include: construction mats, fencing materials, fuel and lubricants, stormwater control materials (straw bales, erosion control fabric, silt fence materials, etc.), and other construction materials. The yards would also be used for contractor office trailers and employee parking facilities. Although the yards are previously disturbed industrial sites, there is some unknown level of risk that stored materials and surface runoff could enter SONCC coho critical habitat.

PCGP has consulted with the BLM, the Forest Service, and the NRCS regarding erosion control and revegetation specifications. Other appropriate agencies have been consulted as well. The Oregon Department of Agriculture (ODA) Noxious Weed Control Program, as well as the BLM and the Forest Service, have been contacted regarding recommendations for the prevention and spread of noxious weeds with those incorporated into the Pipeline project-specific ECRP. Pursuant to FERC's Wetland and Waterbody Procedures (see section IV.A), PCGP has prepared a SPCC Plan (see appendix L). The Plan includes identifying all potential spill hazards at the facility (including oil) and lists the appropriate response actions and contacts for facility and emergency response personnel. All station technicians would be trained for proper handling, storage, disposal, and spill response of hazardous).

Operation and Maintenance Activities

Once installed, maintenance of the pipeline would include activities such as aerial inspections, gas flow monitoring, visual inspection of surrounding vegetation for signs of leaks, and integrity management, which includes smart pigging to investigate the interior surface of the pipe for any signs of stress cracking, pitting, and other anomalies (see the ECRP, appendix F). All of the proposed maintenance activities would be outlined in the Operations and Maintenance Plan that would be prepared according to operating regulations in DOT 49 CFR Subpart L, Part 192 and would be completed prior to going in-service. These general maintenance activities would require only surface activities and usage of the existing right-of-way, such as insertion of the pig at one of the pig launching facilities.

Potential stream channel disturbance would occur if an integrity issue with the pipeline was found. If this were to occur, the pipeline would need to be unearthed within the right-of-way and repair work done in-water. Within stream sites, repair work could require isolated flow from the section of pipe that is to be exposed. Typically, repairs would be made to the pipe within the right-of-way (within the trench) or, depending on the site-specific conditions and nature of the repair needed, a reroute around the affected section may be considered.

Impacts would be similar to those discussed above for initial installation except on a much smaller scale, because they would only involve one crossing compared to many streams. However, should repairs be needed out of the standard stream crossing window (i.e. during periods of fish spawning or egg incubation) there would be additional adverse effects to key fish resources at the specific site. The actions would include all relevant BMPs and mitigation, dependent upon site conditions and land ownership. Any future repairs would require additional permit approval from appropriate state and federal agencies that would determine the acceptable parameters of these actions. Such pipeline integrity-based in-water projects are very infrequent.

Vegetation maintenance would be limited adjacent to waterbodies to allow a riparian strip to permanently revegetate with native plant species across the entire right-of-way. To facilitate periodic pipeline corrosion/leak surveys, a corridor centered on the pipeline and up to 30 feet wide would be maintained in an herbaceous state, with shrubs outside of this 30-foot corridor. In addition, trees that are located within 15 feet of the pipeline may be cut and removed from the right-of-way. No vegetation or tree limitations would occur beyond the 30-foot wide corridor in riparian areas (i.e., up to 100 feet of streams on federal lands, and 25 feet on non-federal lands).

<u>Herbicide Application</u>

Herbicides have the potential to cause toxic effects to different salmonid life stages and to other aquatic species, causing direct impacts, if used improperly. When herbicides are properly used according to label restrictions and BMPs to control noxious weeds, there is little to no chance of causing injury or mortality to fish or other aquatic organisms.

PCGP would not use herbicides for routine vegetation maintenance. However, following construction, PCGP would implement the integrated pest management plan (IPM ,see appendix N to PCGP's POD), which addresses control of noxious weeds and invasive plants across the Pipeline project which would include the selective use of herbicides where necessary to control noxious weeds by limited application from the ground, where allowed by landowners. The plan was developed in consultation with the ODA, BLM, and Forest Service. Herbicides have the potential to cause toxic effects to different salmonid life stages and to other aquatic species, causing direct impacts, if used improperly

The BMPs would minimize the potential spread of invasive species and minimize the potential adverse effects of control treatments. Herbicides would not be applied by aerial or broadcast spraying. Noxious weeds would be removed only by manual methods in the riparian zone defined as one site-potential tree height and within Riparian Reserves that are defined as being greater than 150 feet in most areas along the route. PCGP would not directly spray, or otherwise apply, herbicides in waterbodies or in riparian zones. The risk of drift would be avoided by selectively applying herbicides from the ground.

Where weed control is necessary along the construction right-of-way, PCGP's first priority would be to employ hand and mechanical methods (pulling, mowing, biological, disking, etc.) applicable to the species to prevent the spread of potential weed infestations, where feasible. To determine if an herbicide is to be used over other control methods, PCGP would base the decision on weed characteristics and integrated weed management principles (Forest Service 2005). If herbicides are used to control noxious weed infestations, they would be used when they are the most appropriate treatment method. Spot treatments and the use of selective herbicides would be utilized to minimize impact to native or non-target species. Permits or approvals for the use of herbicides and adjuvants on federal lands would be obtained prior to use/treatment, as detailed in the IPM (see appendix N to the POD). Considering the potential for limited use of herbicides along the route, and precautions that would be in place to prevent entry into waters, meaningful negative effects to SONCC coho salmon from herbicides would be unlikely to occur.

Cumulative Effects

Cumulative effects in the marine analysis area were presented in the green sturgeon section (3.5.1.3) and would be similar for SONCC coho salmon. These effects include increased boat traffic in coastal Pacific Ocean and the associated potential for increases in noise and fuel and oil spills. The increase in vessel traffic would be slight, as noted in section 3.5.1.3. The slight increase would result in a greater risk of noise impacts on SONCC coho salmon; however, because Project effects are expected to be minor, cumulative effects in the marine analysis area are expected to be insignificant. It appears that the background rate of spills (oil, diesel fuel) off the Oregon coast (incidence of spills in proportion to total vessel operation) by fishing vessels, recreation vessels, and other vessel types is generally low. Based on existing information, future rates of off-shore releases are also expected to be low, and therefore, the potential for SONCC coho salmon to be affected by oil and other pollutants is not expected to increase above existing levels.

Cumulative effects to SONCC coho salmon in the riverine analysis area would be generated by timber harvesting on non-federal lands because there is no federal nexus requiring ESA consultations. Areas of LSOG forest have been monitored as a component of the NWFP. In

Oregon, LSOG was evaluated in 1996 (Moeur et al. 2005), in 2006 (Moeur et al. 2011), and in 2013 (Davis et al. 2015). Differences in areas of LSOG forests were described in the four physiographic provinces that coincide with the Pipeline project; from 1993 to 2012, there was an overall net loss of LSOG on non-federal lands within the Coast Range, Klamath, and Western Cascades and Eastern Cascades provinces (see Table 7 in Davis et al. 2015). During that period, areas of LSOG on non-federal lands decreased by 29 percent within the Trail Creek Watershed but increased by 51 percent within the Shady Cove-Rogue River Watershed, increased by 34 percent in the Big Butte Creek Watershed, and increased by 148 percent in the Little Butte Creek Watershed. These changes in areas of LSOG from 1993 to 2012 are clearly evident in figure 3.5.3-6 and are somewhat anomalous compared to other areas with the NWFP. For example, LSOG forest decreased by 26.8 percent between 1993 and 2012 in the Oregon Coast Range physiographic province, decreased by 22.3 percent in the Oregon Western Cascades, decreased by 10.1 percent in the Klamath, and decreased by 14.1 percent in the Oregon Eastern Cascades provinces (Table 7 in Davis et al. 2015).

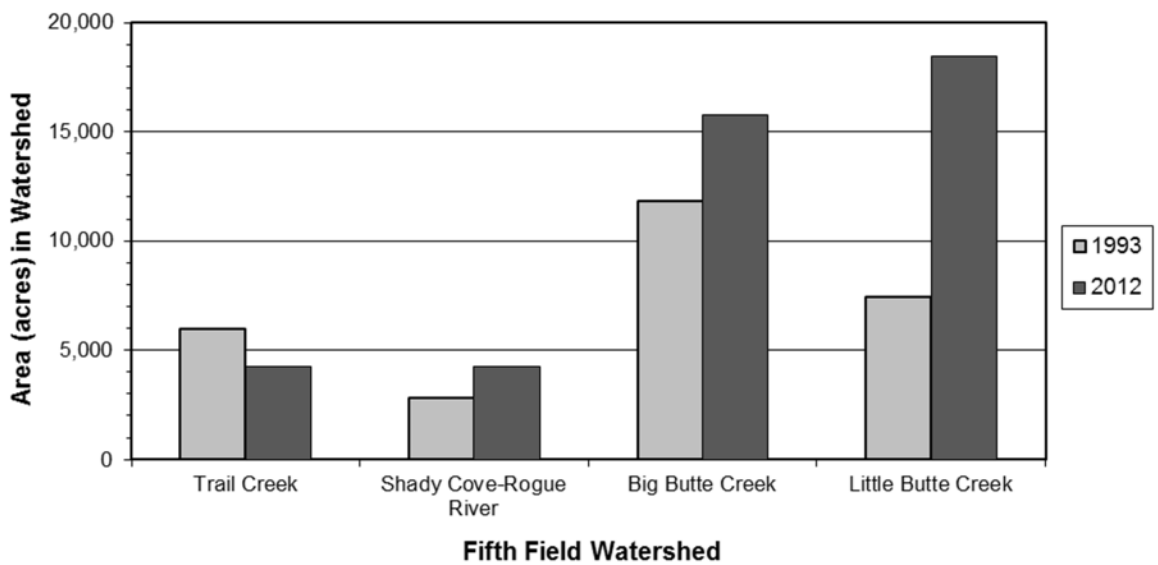

Figure 3.5.3-6 Total Areas (acres) of Late Successional-Old Growth Forests on Non-Federal Lands in 1993, and 2012 within Four Fifth-Field Watersheds in the Range of SONCC Coho Salmon that would be Crossed by the Pipeline Project. (Data from NWFP Interagency Regional Monitoring Program 2017)

Declines in LSOG were as dramatic or more pronounced on non-federal lands in the physiographic provinces during that same period from 1993 to 2012 (Table 9 in Davis et al. 2015). However, based on the past trend, there would be more LSOG 80 years and older on non-federal lands in the foreseeable future due to forest succession (Davis et al. 2015) within three of the four watersheds, including more LSOG within riparian zones. Changes in LSOG within riparian zones on non-federal land would be a reasonably foreseeable cumulative impact through the year 2020 (potentially the Project start). Based on the information provided by Davis et al. (2015), the amount of LSOG on non-federal land through 2020 would be expected to change at the same rate (acres per year) as the amounts that have changed (increased or decreased) between 1993 and 2012. Changes in area of LSOG within the four fifth field watersheds by the same rate of change observed between 1993 and 2012 were used to predict areas of LSOG in 2020, which, depending on the watershed, are expected to decrease or increase within the four watersheds crossed within the range of SONCC coho (see table 3.5.3-32).

TABLE 3.5.3-32

Estimates for Areas of Late Successional-Old Growth Forest in 2020 on Non-Federal Lands in Fifth-Field Watersheds Crossed by the Pipeline Project

Subbasins and Fifth-Field Watersheds	Area (acres) of LSOG on Non-Federal Land: 1993 a/	2012 b/	Change in Area from 1993 to 2012	Proportional Change in LSOG per year since 1993	Estimated Area (acres) of LSOG in 2020
Upper Rogue Subbasin					
Trail Creek	5,963	4,222	-1,742	-0.015	3,351

a/ Data from Regional Ecosystem Office 2017 and Moeur et al. 2005.
b/ Data from NWFP Interagency Regional Monitoring Program 2017 and Davis et al. 2015.

Amounts of LSOG within the Pipeline project area that would be affected by construction and amounts of LSOG that would be affected within riparian zones (e.g., see table 3.5.3-25a) have been determined. The areas (acres) of all LSOG on non-federal lands within riparian zones 1 SPTH wide are provided in table 3.5.3-25a for each watershed. The data were derived by buffering all streams within each watershed (data from National Hydrography Dataset, USGS 2016) by the 1 SPTH riparian zone widths in table 3.5.3-25a in combination with old growth, 80 years and older spatial data in 2012 (NWFP Interagency Regional Monitoring Program 2017 and Davis et al. 2015) and land ownership. The amounts of LSOG forest within non-federal lands in riparian zones that would be removed during Pipeline construction were provided above in table 3.5.3-25a and included in table 3.5.3-33. The Pipeline project would affect less than one percent of the amount of LSOG (estimated for 2017) on non-federal lands in riparian zones for all streams in each fifth field watershed. With the estimates for areas of LSOG present in 2020, based on proportional changes in areas observed between 1993 and 2012 (table 3.5.3-32), an estimate for area of LSOG on non-federal lands in riparian zones for all streams in each fifth field watershed in 2020 is included in table 3.5.3-33. With the overall increase in LSOG expected between 2017 and 2020, the relative effects of Pipeline construction on available riparian LSOG would be expected to decrease from current estimates on nonfederal lands in the foreseeable future.

TABLE 3.5.3-33

Potential for Cumulative Effects within Late Successional and Old-Growth Riparian Forests on Non-Federal Lands within the SONCC Coho Salmon ESU Riverine Analysis Area

SONCC ESU Fifth-Field Watershed	Area (acres) of Riparian LSOG on Non-Federal Land in 2012 a/	Area (acres) of Riparian LSOG Present on Non-Federal Land in 2017 b/	Area (acres) of Riparian LSOG Affected on Non-Federal Land in 2017 c/	Percent of Riparian LSOG Affected by Project in 2017 d/	Area (acres) of Riparian LSOG Estimated in 2020 b/	Percent of Riparian LSOG Affected by Project in 2020 e/

a/ Data from NWFP Interagency Regional Monitoring Program 2017.
d/ Based on the Proportional Change in LSOG per year since 1993 in table 3.5.3-32
c/ Data from table 3.5.3-25a.
d/ For comparison to effects in 2020.
e/ Based on Area of riparian LSOG Estimated in 2020 that would be affected by Pipeline project on non-federal land in 2020.

Critical Habitat

Eight waterbodies known to support coho within table 3.5.3-3 that would be affected by construction of the Pipeline are within designated critical habitat for coho salmon in the SONCC ESU. Critical habitat is designated to include all river reaches accessible to listed coho within the range of the SONCC ESU. Critical habitat consists of the water, substrate, and adjacent riparian zone of estuarine and riverine reaches in hydrologic units and counties identified in NMFS (1999b), including the Upper Rogue HUC 1700307. Accessible reaches are those within historical range of the ESUs that can still be occupied by any life stage of coho salmon.

Riparian Zone Effects. Similar analyses to those above under Riparian Vegetation Removal and Modification were conducted for effects to riparian zones associated with each waterbody supporting coho critical habitat and waterbodies that are assumed to provided coho in each watershed. Areas of forested and non-forested habitats that would be affected within the riparian zones of each waterbody during construction are provided in table 3.5.3-34a and areas affected during operation are provided in table 3.5.3-34b and summarized in table 3.5.3-34c. The tables also include riparian zone areas affected by landowner, similar to tables 3.5.3-25a and 3.5.3-25b.

a/ Project components considered in calculation of habitat "Removed:" PCGP construction right-of-way, temporary extra work areas, aboveground facilities, and permanent and temporary access roads (PAR, TAR).

b/ Habitat Types within Riparian Zones generally categorized as: Late Successional (Mature) or Old Growth Forest (coniferous, deciduous, mixed ≥80 years old); Mid-Seral Forests (coniferous, deciduous, mixed ≥40 but ≤80 years old); Regenerating Forest (coniferous, deciduous, mixed ≥5 but ≤40 years old); Clearcut Forests; Forested and Nonforested Wetland, Unaltered Nonforested Habitat (grasslands, sagebrush, shrublands), Agriculture, and Altered Habitats (urban, industrial, residential, roads, utility corridors, quarries).

Effects to water temperature (shade) during construction and operation within the riparian zone of each waterbody assumed to support coho or with coho critical habitat are assumed to be directly related to areas of riparian forest removed during construction (riparian forest within the construction right-of-way, TEWAs, TARs, and PARs) and to areas of riparian forest that would be removed within the 30-foot wide operational easement for the life of the Pipeline. Riparian forest that is not in the operational easement would be restored over time, presumably attaining mid-seral status (40-80 years old) at the end of the 50-year life of the Pipeline. Magnitude of impact to riparian shade associated with each waterbody with critical habitat and assumed to be occupied by coho is directly related to the absolute and relative amounts of riparian forest removed during construction, amounts removed permanently by the operational easement, and amounts of riparian forest that would be restored within affected riparian zones.

Table 3.5.3-34c below, summarizes tables 3.5.3-34a and 3.5.3-34b. The greatest absolute impact to shade within riparian zones associated with critical habitats for SONCC coho would occur at Canyon Creek with removal of 1.09 acres of riparian forest. Riparian zones of Canyon Creek and Tributary to Trail Creek, both within the Trail Creek Watershed, and Quartz Creek within the Big Butte Creek watershed would have relatively large amounts of riparian forest affected during construction but relatively large areas of forest restoration following construction would partially offset the effects of construction. Absolute and relative impact to forests within riparian zones (with concomitant effects to water temperature and shade) associated with other affected waterbodies with critical habit for SONCC coho would be more modest (or nearly zero). The longest-term effects to riparian forest would occur at Canyon Creek and Tributary to Trail Creek (Trail Creek Watershed) where 1.09 acres and 0.50 acre of late successional-old growth forest would be removed, respectively.

TABLE 3.5.3-34c

Summary Table for Effects to Riparian Zones

a/ Summarized from table 3.5.3-25a
b/ Summarized from table 3.5.3-25b

Effects to LWD during construction and operation within the riparian zone of each waterbody assumed to support coho or with coho critical habitat are assumed to be directly related to areas of riparian forest removed during construction (riparian forest within the construction right-of-way, TEWAs, TARs, and PARs) and to areas of riparian forest that would be removed within the 30-foot wide operational easement for the life of the Pipeline. Riparian forest that is not in the operational easement would be restored over time, presumably attaining mid-seral status (40-80 years old) at the end of the 50-year life of the Pipeline. Magnitude of impact to LWD recruitment associated with each waterbody with critical habitat and assumed to be occupied by coho is directly related to the absolute and relative amounts of riparian forest removed during construction, amounts removed permanently by the operational easement, and amounts of riparian forest that would be restored within affected riparian zones. The Pipeline project would result in adverse effects to freshwater critical habitat for the SONCC ESU of coho salmon. Most effects would be short-term, but some would be intermediate to long-term. Minor short-term effects would occur from sedimentation during construction actions. Minor intermediate-term effects would occur from a reduction in riparian habitat due to construction and operation. Sediment disturbance at stream crossings would affect food sources for rearing fish in the short-term, and riparian plant removal would reduce LWD supply affecting habitat quality and quantity in the intermediate to long-term over small stream areas (i.e., within the less than 75 to 95-foot stream length clearing area per crossing).

Within the range of the SONCC ESU, the coho life cycle can be separated into five essential habitat types: 1) juvenile summer and winter rearing areas; 2) juvenile migration corridors; 3) areas for growth and development to adulthood; 4) adult migration corridors; and (5) spawning areas. Within these areas, essential features of coho salmon critical habitat include: adequate 1) substrate, 2) water quality, 3) water quantity, 4) water temperature, 5) water velocity, 6) cover/shelter, 7) food, 8) riparian vegetation, 9) space, and 10) safe passage conditions (NMFS 1999b). Each element or feature defined for critical habitat could be adversely affected by the proposed action. Those effects have been quantified to the extent possible in the foregoing analyses and summarized below in table 3.5.3-35.

Project effects to freshwater spawning sites would likely occur prior to coho spawning in the year of construction, and there would be no effects to spawning, incubation, and larval development by suspended sediment although Pipeline project-generated sediment could increase gravel embeddedness downstream. Those effects would depend on precipitation and in-stream flow (potential freshets) following construction that would likely flush fines downstream. The Pipeline project would remove small areas of riparian forest that would provide recruitment of LWD. The Pipeline project would temporarily decrease water quality downstream from construction sites by entrainment of sediments and temporarily limit in-stream migration during in-stream construction. In all instances, habitat suitability (HADD, Anderson et al. 1996) would temporarily decrease, though not necessarily to levels that would cause moderate habitat degradation (SEV = 7).

TABLE 3.5.3-35

Summary of Project Effects to Critical Habitat Designated for SONCC Coho within Watersheds Crossed by the Pipeline Project

Subbasins and Fifth-Field Watersheds	Total Waterbodies Crossed in Watershed	Waterbodies with Coho Affected a/			Riparian Zone Width (feet) b/	Areas (acres) of Riparian Vegetation Removed in Critical Habitat c/		
		Documented	Assumed	Total with Critical Habitat /b		Forested Habitat	Non-forested Habitat	Total
Upper Rogue Subbasin								
Trail Creek	6	3	0	3	159	2.08	1.34	3.42
Shady Cove-Rogue River	11	1	1	1	157	0.32	0.85	1.17
Big Butte Creek	9	2	0	2	187	1.06	1.02	2.09
Little Butte Creek d/	46	2	2	2	158	0.52	3.21	3.73
Total	**72**	**8**	**2**	**8**		**3.99**	**6.42**	**10.41**

a/ Data from ODFW GIS database (ODFW 2017f).
b/ Based on presence and potential presence (assumed) of SONCC coho.
c/ Riparian width of 1 SPTH, one site-potential tree height.
d/ Includes the Key Watershed designated within the Little Butte Creek 5th field watershed.

3.5.3.4 Conservation Measures

Appendices N and O include a complete list of conservation measures proposed by JCEP and PCGP. Conservation measures proposed by PCGP to minimize construction and operation impacts to waterbodies and riparian zones within the riverine analysis area are listed in tables 1 and 2C in appendix N. PCGP has also proposed measures to rectify, repair, rehabilitate, and otherwise reduce impact to waterbodies and riparian zones once construction of the Pipeline is complete. Those measures have been compiled in table 3C in appendix N. Details of some of the major conservation measures applicable to SONCC ESU to be implemented by PCGP are summarized below.

Erosion Control

Many of the conservation measures in table 3C in appendix N focus on erosion control to prevent sediment from entering surface waters. Temporary erosion controls would be installed immediately after vegetation clearing and grading and would be properly maintained throughout construction and reinstalled as necessary until replaced by permanent erosion controls or restoration is complete. At a minimum, the following temporary erosion control structures would be installed: temporary slope breakers, sediment barriers, mulch, and erosion control fabric. PCGP would install permanent slope breakers consistent with the requirements of FERC's *Plan*. Part of long-term erosion control would include a final cleanup including final grading and installation of permanent erosion control structures. Final cleanup of an area would generally occur within 10 days after backfilling the trench and not be delayed beyond the end of the next recommended seeding season. During final cleanup, PCGP would remove all construction debris and grade disturbed areas to preconstruction grades to the extent practicable. An adequate seedbed would be prepared at the conclusion of cleanup.

<u>Temporary Slope Breakers</u>

PCGP would install temporary slope breakers over the backfilled, recontoured construction right-of-way as specified in FERC's *Plan*. The outfall of each temporary slope breaker would be to a stable, well-vegetated area or to an energy-dissipating device at the end of the slope breaker off the construction right-of-way. Slope breakers reduce runoff velocity, thereby intercepting sediment and allowing it to drop out of suspension. They also can effectively divert runoff away from a disturbed site to a stable outlet (Goldman et al. 1986).

Sediment Barriers

PCGP would primarily rely upon silt fence and staked hay or straw bales to confine sediment to the construction right-of-way. These structures would be used adjacent to wetland and waterbody crossings consistent with the requirements of FERC's *Procedures*. Straw bales and filter fabric (silt fence) can be used together to create a highly effective sediment barrier, a combination that compensates for the limitations of each used in isolation; straw bales provide extra support and the fabric provides greater filtering capability (Goldman et al. 1986).

All straw or hay bales used for sediment barriers would be certified as weed-free. Temporary sediment barriers would be maintained in-place until permanent revegetation measures are successful or until the upland areas adjacent to wetlands, waterbodies or roads are stabilized. The structures would be removed once vegetation in the area has been successfully restored.

Erosion Control Fabric

PCGP would install erosion control fabric (such as jute or excelsior) on waterbody banks at the time of recontouring. The fabric would be anchored using staples or other appropriate devices. Although there are no measures specific to pipeline construction, data related to cut-and-fill slopes treated during construction of forest roads indicate varying effectiveness of different types of stabilization measures designed to control surface erosion (EPA 2001). On fill slopes, combining straw mulch and netting decreased erosion by 99 percent. Excelsior mulch alone decreased erosion by 92 percent on fill slopes. On cut slopes, straw mulch by itself decreased erosion in a range from 32 to 97 percent (EPA 2001). Applications of mulches and/or fabric are effective measures promoting slope stabilization until vegetation can successfully be reestablished. These measures also promote plant growth (EPA 2001).

Fish Salvage Plan

All waterbodies that would be crossed by dry open-cut construction would be done prior to adult coho salmon upstream migration, within ODFW in-stream construction windows. A *Fish Salvage Plan* has been provided in appendix T. The plan has been developed to minimize adverse effects to listed salmonids (SONCC coho salmon, Oregon Coast coho salmon), non-listed salmonids (Chinook salmon, steelhead, and cutthroat trout) and listed catostomids (Lost River sucker, shortnose sucker). The portions of the plan relevant to salvaging salmonids were adapted from the protocol developed by WSDOT (2012). The protocol specifies procedures to 1) isolate the work area; 2) remove fish and dewater the work area; 3) handle, hold and release fish; 4) document fish that have been captured, handled, held, and released; and 5) notify NMFS and FWS. Only trained professionals would conduct electroshocking and fish removal.

Revegetation

As required by FERC's *Plan*, PCGP has identified procedures for the preparation and planting of live stakes or sprigs and for the planting bare root tree seedlings. Those procedures are included in appendix R. Within the range of SONCC coho salmon, construction of the Pipeline would remove 41.59 acres of riparian forested habitats of which 20.24 acres are late-successional (mature) old-growth, 17.97 acres are mid-seral forests, and 0.08 acres are forested wetlands. Within the Trail Creek watershed 6.17 acres of riparian forest would be removed; 8.01 acres within the Shady Cove-Rogue River watershed; 5.74 acres within the Big Butte Creek watershed; and 21.67 acres within the Little Butte Creek watershed (see table 3.5.3-25a).

Existing forested riparian zones in which forest would be removed during construction would be re-planted with conifers to within 15 feet of each side of the centerline. Permanent effects – persisting longer than the assumed 50-year life of the Pipeline – would occur by removing 16.86 acres of late-successional (mature) old-growth riparian forest. Even though the riparian zone would be replanted, the newly planted trees would not attain late-successional or old-growth status within 50 years. Permanent effects would also last along the 30-foot-wide maintenance corridor centered on the Pipeline. Those effects to former late-successional (mature) old-growth riparian forest, mid-seral riparian forest and other existing riparian vegetation are included in table 3.5.3-25b. Due to a maintenance access route in the right-of-way that would not be allowed to grow trees for the life of the Pipeline project, replanting conifers in the remaining affected forested riparian zone would still leave an estimated 10.02 acres of non-forested vegetation within former forested riparian zones over the long-term or permanently (see table 3.5.3-25b).

OHV Barriers

Limiting OHV vehicle access would reduce potential increased sedimentation to streams and human access to sensitive fish areas. In accordance with FERC's *Plan*, the applicant would offer to install and maintain measures to control unauthorized vehicle access to the right-of-way to each landowner or manager of forested lands. Such measures may include signs; fences with locking gates; slash and timber barriers, pipe barriers, or a line of boulders across the right of way; and conifers or other appropriate trees or shrubs across the right-of-way. If allowed by the landowner, and if available, slash, stumps and or logs would be placed on the right-of-way within the riparian zones to discourage OHV crossings of streams and provide carbon and nutrients. If not allowed, PCGP would discuss with the landowner the use of other methods, as noted above. At a minimum the area would be revegetated and re-seeded.

Streambank Stability

The root network of trees adjacent to streambanks is essential to maintaining streambank stability (WDNR 1997). Because root strength decreases significantly at distances beyond one-half the tree crown diameter, trees promoting streambank stability lie within half a tree crown diameter from the streambank. Trees within 25 feet of the streambank are assumed to promote streambank stability (WDNR 1997). Generally, trees that must be removed during construction would be cut at ground level with the roots left in place, except where located within the trench line. Although roots would decay overtime, streambank stability would be retained by their presence until revegetation is successful.

Streambank Restoration

PCGP's ECRP (see appendix F) describes the measures that would be used to stabilize streambanks crossed by the Pipeline. PCGP would not use riprap to stabilize streambanks. The alignment has been designed at waterbody crossings to be as perpendicular to the axis of the waterbody channel, as engineering and routing constraints allow, minimizing streambank disturbance and avoiding parallel stream alignments or multiple stream crossings. Immediately after installation of a waterbody crossing, the contours of the streambed, shoreline, and streambanks would be restored to preconstruction configurations (i.e., contour/elevations) to restore the physical integrity/condition of these features and to minimize the loss of stream complexity.

PCGP has completed a scour analysis that would be used to ensure that appropriate pipeline burial depths and cover design parameters beneath channel streambeds and adjacent floodplains are utilized, so that the effects on natural stream processes would be avoided or minimized (GeoEngineers 2017i).

PCGP would install erosion control fabric (such as jute or excelsior) on streambanks at the time of recontouring. The fabric would be anchored using staples or other appropriate devices. The erosion control fabric to be used on streambanks would be designed for the proposed use and would be approved by PCGP's EIs.

Consistent with the FERC's *Procedures* (section V.C.3.), during streambank restoration/recontouring, the streambanks would be returned to their preconstruction contours or to a stable configuration. Streambank revegetation measures, including supplemental riparian planting procedures are also outlined in the ECRP. The shrubs and trees planted at each site would be determined at the time of planting based on the moisture regimes and site-specific conditions at each planting location and landowner requirements.

In-stream Gravel

Waterbodies supporting fisheries would be backfilled with material removed from the trench with the upper 1 foot of the trench backfilled with clean gravel or native cobbles. PCGP has requested a variance from section V.C.1. of FERC's *Procedures* in fish-bearing streams that do not have gravel, cobble, or other rock substrates prior to construction. This variance was requested because many of the streams crossed by the Pipeline are remote and are located in steep valley or ravine bottoms. Therefore, hauling rock to these steams is impractical, especially where these streams do not have gravel or cobble substrate characteristics prior to construction. The bottom and banks would be returned to preconstruction contours; banks would be stabilized; and temporary sediment barriers would be installed before returning flow to the waterbody channel.

Large Woody Debris

As discussed in the Direct and Indirect Effects section above, mitigation would contribute to restoring an aquatic habitat indicator's functional level, such as placement of LWD within and/or adjacent to streams and placing LWD on floodplains, where appropriate, to provide microsites for riparian vegetation and/or vegetation protection during flood events. Placement of LWD in streams and/or on streambanks has been one focal point of recent stream rehabilitation procedures (Slaney and Martin 1997; Cederholm et al. 1997; EPA 2001) and is further described in the *Large Woody Debris Plan* (appendix O).

As indicated in table 3.5.3-8, baseline watershed conditions crossed by the Pipeline are lacking in LWD due to historical disturbance, and LWD presence is typically below benchmark thresholds to be properly functioning. LWD is an important habitat feature providing in-stream structure, channel and habitat complexity, among other benefits, and one that promotes salmonid productivity. If approved by land owners, PCGP proposes to install LWD on-site during construction as an appropriate habitat enhancement feature to mitigate for potential impacts and to benefit watershed conditions, which are generally lacking.

LWD placement would be in addition to the conservation measures (see appendix N) that have been designed to minimize the potential effects, including utilizing dry open-cut crossing methods, applying in-stream construction timing restrictions, and implementing erosion control measures and revegetation methods. Because of the overall lack of LWD in the affected watersheds, LWD also provides an appropriate mitigation model for the potential waterbody crossing impacts that are temporary, short-term, and unavoidable (see the *Large Woody Debris Plan* in appendix O). The LWD would also serve to mitigate for potential long-term impacts—impacts lasting for the 50-year life of the Pipeline—such as the loss of forested riparian vegetation within the 30-foot operational corridor (see table 3.5.3-25b). Even though the riparian zone would be replanted, the planted trees would not attain late-successional or old-growth status within 50 years. Placement of LWD would, in some measure, reduce, though not eliminate, the impact due to the removal of LSOG riparian forest.

For low-gradient streams, Cederholm et al. (1997) suggest using logs with diameters at least 18 inches (less in areas of low velocity) placed by vertical angling into the stream channel. Logs could be used to create a stepped-channel profile with the rootwads and encourage woody debris accumulations in pool margins. For streams with steeper gradients, Cederholm et al. (1997) suggest that logs with smaller diameters might be used if larger logs are unavailable. Near headwaters, LWD is often suspended over the channel so that it can become functional during periods of maximum runoff. Smaller debris may be retained during those periods and help develop pools that would be functional during summer (see Cederholm et al. 1997).

Guidelines for LWD placement, provided by ODF and ODFW (1995), suggest using the following: 1) larger diameter wood pieces because they are more effective at creating pools and complex channels which improve fish populations (see table 3.5.3-36 for minimum diameter LWD per bankfull width); 2) LWD that are at least twice the length of the waterbody bankfull width (1.5 times the bankfull width if the rootwad is attached) to increase the likelihood that the LWD would remain in place; and 3) conifer logs, especially western red cedars if available, because they are more durable. In larger waterbodies, smaller diameter, shorter LWD could be used if bundled and anchored together to provide the same benefits of the longer, larger diameter LWD (ODF and ODFW 1995).

TABLE 3.5.3-36

Minimum Diameter LWD for Placement in Waterbody Based on Bankfull Width

Bankfull Width (feet)	Minimum Diameter LWD (inches)
0 to 10	10
10 to 20	16
20 to 30	18
Over 30	22

Source: ODF and ODFW 1995.

Trees classified as late successional or old growth are assumed to have attained heights equal to the site-potential tree heights that are included above in table 3.5.3-35 as Riparian Zone Widths. Site-potential tree heights range from 157 feet (for example, the Shady Cove-Rogue River Watershed) to 187 feet (as in the Big Butte Creek Watershed). If Douglas-fir trees in the Oregon Cascades grow in height at the rate of 20 inches per year and in diameter by 0.25 inch per year (Cox 2008), a 20-inch-tall seedling planted the year after construction would be an estimated 85 feet tall and 12 to 13 inches in diameter (assumed dbh) after 50 years. Trees with those dimensions would provide suitable LWD for streams with bankfull widths from 0 to 10 feet but not larger streams (see table 3.5.3-36). Even in these streams recruitment of wood may be reduced as the rate for natural mortality of the young forest would be less relative to older trees. Although, recruitment of wood is not solely dependent on natural tree mortally and includes important contributing factors such as bank erosions, disease, fires, slides, and windthrow (Reeves et al. 2003; Martin and Benda 2001; Gregory et al. 2003). LWD contribution would occur from these areas even though natural mortality contribution would be reduced.

The Pipeline would cross 13 perennial streams within the range of SONCC ESU coho salmon. Twelve of those perennial streams have existing riparian forest ranging from clear-cut forest to mid-seral stage (approximately 40 to 80 years old) and older late-successional and old-growth stages; 6.91 acres of existing riparian forest associated with perennial streams would be removed by construction. One additional perennial stream would also be crossed but construction would not affect riparian forest vegetation (see table 3.5.3-37). In addition, the Pipeline would cross 52 intermittent streams, 41 of which support riparian forest, and would affect riparian forest of 19 other intermittent streams; 41.68 acres, total, of riparian forest at perennial and intermittent streams would be removed. Seventeen intermittent streams with no riparian forest would also be crossed (see table 3.5.3-37).

To offset impact from removal of riparian trees (reducing LWD recruitment potential) and to provide an overall benefit by enhancing stream habitat with no potential for LWD recruitment, PCGP proposes to place LWD at the waterbody flow types identified by watershed in table 3.5.3-37 (see the *Large Woody Debris Plan* in appendix O), based on the following applications:

- four pieces for each perennial stream crossed with riparian forest removed (two pieces in-stream and/or keyed into the streambank, two pieces within riparian zone on the bank);
- two pieces for each intermittent stream and unknown stream crossed with riparian forest removed (one or both LWD pieces placed in-stream, keyed into the bank, or placed on the bank);
- two pieces for each perennial, intermittent, and unknown stream crossed but with no riparian forest removed (one or both LWD pieces paced in-stream keyed into the bank, or placed on the bank); and
- one piece each for a perennial, intermittent, and unknown stream not crossed but adjacent to the construction right-of-way, with or without riparian forest removed (LWD placed on bank).

Because the construction right-of-way at stream crossings would be 75 to 95 feet wide, PCGP anticipates only enough space for two pieces of LWD, preferably with rootwads attached, either placed in-stream or with stems keyed into streambanks. Unless site-specific conditions dictate otherwise, the preferable location for each in-stream LWD is downstream from the pipeline to prevent scour of the pipe. LWD would also be placed near or adjacent to streambanks within riparian zones to provide for and/or enhance microsites for riparian vegetation and/or vegetation protection during flood events.

The LWD plan includes placing from 1 to 4 pieces of LWD per stream crossed in the stream or on the bank, depending on forest conditions, stream flow, and landowner approval. This number of pieces, if no other LWD were present in the stream reach affected by clearing, would be in the range of what is considered "desirable" by ODFW (Foster et al. 2001) for forested streams. Foster et al.

(2001) noted that more than 20 LWD pieces/100 meters of stream length (i.e., 4.6 pieces/75 feet of right-of-way clearing) with more than 3 "key" pieces/100 meters (i.e., 0.7 "key" pieces/75 feet right-of-way clearing) is considered "desirable" in forested streams in Oregon. The sizes of LWD pieces to be installed are shown in table 3.5.3-36 above in streams to meet habitat needs for specific stream sizes and number of streams crossed.

In all, PCGP proposes 173 pieces of LWD for placement within the four fifth-field watersheds that coincide with SONCC ESU coho salmon and designated critical habitat. Placement of LWD is subject to approval by each affected landowner. If a landowner rejects the proposed placement of LWD, the number of pieces that would have been applied onsite would be reserved and provided to appropriate watershed councils for their use and placement, preferably elsewhere within the affected fifth-field watershed.

PCGP anticipates that during construction, in some cases, the waterbody size, landowner restrictions, or construction constraints would limit LWD placement according to the proposed LWD schedule provided in table 3.5.3-37. Further, the overall benefit of installation of LWD at some waterbody crossings (i.e., intermittent headwater streams) may not warrant LWD placement. In these situations, PCGP's EI would record the uninstalled LWD as a deficit during construction. After construction is completed, unutilized LWD would be provided to local watershed conservation organizations or agencies for use in local enhancement projects within the affected watersheds. (Also see the discussion on the use of LWD for mitigation in appendix O.)

TABLE 3.5.3-37

Proposed Application of Large Woody Debris to Waterbodies and Riparian Zones Affected by Construction of the Pipeline within the Range of Southern Oregon Northern California Coast Coho Salmon

Fifth-Field Watershed	Watershed Parameter a/	Waterbody Type: Perennial Crossed	Perennial Adjacent	Intermittent Crossed	Intermittent Adjacent	Unknown Crossed	Unknown Adjacent	Total in Watershed	Pieces of LWD Applied to Fifth-Field Watershed b/: Crossed	Adjacent	Total

								Total LWD	**154**	**19**	**173**

a/ Riparian Forest assumed to be coniferous, deciduous, or mixed forest 40 years old and older.
b/ Proposed schedule for applying LWD to different waterbody types, subject to landowner approval:
– 4 pieces for each perennial stream crossed with riparian forest removed (2 pieces in-stream, 2 pieces within riparian zone on the bank);
– 2 pieces for each intermittent stream and unknown stream crossed with riparian forest removed (one or both pieces placed in-stream or on bank);
– 2 pieces for each perennial, intermittent, and unknown stream crossed but with no riparian forest removed (one or both pieces paced in-stream or on bank);
– 1 piece each for perennial, intermittent, and unknown stream not crossed but adjacent to ROW with or without riparian forest removed (placed on bank).

Stream Crossing Monitoring

PCGP's Stream Crossing Risk Analysis (GeoEngineers 2017d, 2017e and 2018a/appendix O.2 to PCGP's Resource Report 2) provides site-specific BMPs to restore streambed and banks for long-term stability and to restore aquatic habitat. This Risk Analysis also provides a stream crossing monitoring plan to ensure long-term success of stream restoration, maintenance of fish passage, and identification of channel erosion, scour or migration that could destabilize the site or expose the pipeline. Streambank revegetation measures are outlined in section 10.0 of the Risk Analysis. Appropriate restoration BMPs, outlined in the Site-Specific Stream Crossing Prescriptions for the Perennial Streams on BLM and National Forest lands (North State Resources 2014), would also be incorporated during construction and restoration in consultation with the agency's authorized representative and PCGP's EI or authorized representative. Monitoring would be conducted at streams based on levels of risk and described in the section Streambank Erosion and Streambed Stability, above.

3.5.3.5 Determination of Effects

Species

The Project **may affect** coho salmon in the SONCC ESU because:

- several life stages and activities of coho salmon (upstream adult migration, juvenile fry rearing, and juvenile smolt out-migration) are expected to occur at various locations in the riverine analysis area during construction and operation of the proposed action.

While several Project actions are not likely to cause adverse effects, effects from Project components that are **likely to adversely affect** coho salmon in the SONCC ESU include those listed below.

- TSS could adversely affect juvenile coho salmon. Exposure of juvenile fry to TSS concentrations during dry open-cut construction (fluming or dam-and-pump) from 2 to 5 hours (see table 3.5.3-21) could potentially exceed SEV 3 (avoidance effects) or SEV 4 (effects to feeding rate) for an estimated 347 to 1,919 meters downstream (see table 3.5.3-23). Such an effect could cause minor physiological stress in juvenile coho salmon (SEV 3) or a short-term reduction in feeding rate and short-term reduction in feeding success (SEV 4).
- If a failure occurs while dry open-cut construction is underway, possible effects to juvenile coho (SEV = 7) could include moderate habitat degradation and impaired homing by fish.
- Construction requiring blasting at 13 streams could cause mortality to fish by rupturing swim bladders. Adult and juvenile fry coho salmon would be removed and/or prevented from being within 50 feet of blasting sites to the maximum extent possible. A worst-case estimate of 67 juvenile fry coho could potentially be salvaged from streams that require blasting.
- Fish salvage would occur within isolated construction sites when adult and juvenile fry coho salmon are present. Coho salmon are considered vulnerable to electrofishing and could be subject to injury and mortality. Fish salvage would primarily rely on

seining but may require electrofishing if other methods are ineffective (refer to the *Fish Salvage Plan*). Seining, electrofishing, and handling may adversely affect SONCC coho salmon. A worst-case estimate of 167 juvenile fry coho could potentially be salvaged from streams crossed by dry open-cut procedures that did not require blasting.

- Lack of LWD is a limiting factor in most streams within range of SONCC coho salmon. Removal of mid-seral riparian forest (40-80 years old) would have long-term effects to recruitment of LWD, and removal of LSOG forest (≥80 years old) would have permanent effects to recruitment of LWD because planted conifers would not attain that age class within the 50-year life of the Project.

Critical Habitat

The Project **may affect** designated critical habitat for coho salmon in the SONCC ESU because:

- the Pipeline crosses designated critical habitat within waterbodies of the Upper Rogue hydrologic unit (HUC 17100307) below the Lost Creek, Willow Creek, and Fish Lake Dams.

Project components are **likely to adversely affect** designated critical habitat for coho salmon in the SONCC ESU because:

- approximately 8.9 acres of native riparian vegetation (forest, wetlands, and unaltered nonforested habitats) and of altered habitat would be removed during construction within riparian zones associated with designated critical habitat. Adverse effects to riparian zones associated with critical habitat would be long-term or permanent depending on whether mid-seral riparian forests (2.1 acres) or LSOG riparian forests (1.6 acres) are removed (provided in table 3.5.3-34a); and
- a failure of crossing isolation structures lasting for 4 hours or more would cause an SEV score of 7 or higher for at least 132 m downstream from dry open-cut crossings within three streams with critical habitat in the Trail Creek watershed (West Fork Trail Creek, Canyon Creek and tributary to Trail Creek, see table 3.5.3-23), at least 397 m downstream within two streams with critical habitat in the Big Butte Creek watershed (Neil Creek and Quartz Creek, see table 3.5.3-23), and at least 554 m downstream in two streams with critical habitat in the Little Butte Creek watershed (Salt Creek and North Fork Little Butte Creek). SEV of 7 would not occur within designated critical habitat in the Shady Cove-Rogue River watershed (Indian Creek) by a failure lasting for 4 hours but could occur if the duration lasted 5 hours or more.

3.5.4 Coho Salmon (Oregon Coast ESU)

3.5.4.1 Species Account and Critical Habitat

Status

The NMFS (1995) conducted a status review of coho salmon in 1995 that led to a proposed listing of several ESUs as threatened, including the Oregon Coast ESU, in 1995. The final listing was delayed due to disagreements about conclusions drawn from available information and the original proposal to list as threatened was withdrawn in 1997. In 1998, the District Court for Oregon determined that NMFS' 1997 withdrawal of the proposed listing status was arbitrary and capricious and vacated the determination. Following the Court decision, NMFS issued a final rule to list the Oregon Coast ESU as threatened in August 1998. That determination was based entirely on information collected prior to the proposed rule in 1997. However, the District Court set aside the 1998 final rule determining threatened status for the Oregon Coast ESU (a result of the Alsea ruling) and NMFS undertook an updated status review of 27 West Coast salmon ESUs in 2003, which included the coho salmon Oregon Coast ESU. During the status review, the Biological Review Team considered the uncertainty of the ESU becoming endangered. Nevertheless, NMFS again proposed listing the coho salmon Oregon Coast ESU as threatened in June 2004 based on the review (NMFS 2006d).

In December 2004, critical habitat was also proposed. NMFS designated critical habitats for several salmon ESUs in a final rule published in September 2005 but critical habitat for the coho salmon Oregon Coast ESU was not included because there had not been a final rule listing the ESU as threatened. In that new proposed rule, the ODFW was conducting an assessment of the population viability of Oregon Coast coho salmon. From that, ODFW concluded that Oregon Coast coho salmon are "inherently resilient at low abundance" and such response would prevent extinction. With that information and other products from the ODFW *Oregon Coastal Coho Assessment,* NMFS withdrew its proposals to list Oregon Coast coho salmon as threatened and to designate critical habitat in January 2006 (NMFS 2006d). In that decision to withdraw the proposed rules, NMFS declared that listing under ESA was not warranted at the time but the decision was challenged in Oregon District Court, which ruled that NMFS' withdrawal be invalidated and remanded to NMFS (Lohn 2007). The present listing status for the Oregon Coast coho salmon ESU is threatened with corresponding critical habitat (NMFS 2008d). After proposing the ESU for listing, withdrawing the proposal, and re-proposing listing the ESU as threatened under scrutiny of Oregon federal district court, NMFS issued a final rule in 2011 (NMFS 2011d) retaining the threatened listing for the coho in the Oregon Coast ESU.

Threats

At the time the Oregon Coast ESU was first proposed for listing as threatened in 1995, threats to West Coast salmon populations were discussed in general but were not specific to the Oregon Coast ESU. The same factors noted above as threats to coho salmon in the SONCC ESU applied to coho salmon in the Oregon Coast ESU.

NMFS published a more recent status review in 2005 (Good et al. 2005). The U.S. District Court found NMFS' 1998 decision, listing the Oregon Coast coho salmon ESU, as unlawful because the ESU includes hatchery and naturally spawned coho salmon but NMFS only considered naturally spawned fish in their decision (Lawson 2005). Following the delisting, multiple parties petitioned NMFS to re-list all stocks within the Oregon Coast ESU as threatened based on new information about coho salmon abundance, variability in survival and abundance, threats to genetic integrity of stocks, and stochastic events including El Niño conditions and floods (Lawson 2005).

The short-term trend in escapement of adult spawners within the Oregon Coast ESU increased substantially in 2001 and 2002, including trends within the Umpqua, Coos, and Coquille Subbasins due to increased marine survival and considerable restrictions on ocean harvests (Lawson 2005, and see discussion below). Alternatively, trends in short-term recruitment were less positive within the ESU, especially in the Coos and Coquille Rivers (Lawson 2005).

In 1994, most coho salmon harvest was prohibited and has been restricted since then, though mortalities still occur coincidentally with Chinook salmon fisheries for hatchery (marked) coho salmon (Lawson 2005). Subsequent analyses indicated that management for a proportional maximum harvest rate of 35 percent resulted in lower risk of extinction for the ESU than management for an escapement goal or quota of 200,000 spawners ESU-wide. As expected, a harvest of zero further reduces extinction risk (Lawson 2005).

Freshwater restoration projects to improve water quality and watershed conditions have been implemented throughout the Pacific Northwest since the late 1990s (e.g., the Coastal Salmon Restoration Initiative in 1997), though measurable results would take time (Lawson 2005). Poor marine survival for Oregon coho salmon began with climatological changes detected in the mid-1970s and worsening in the 1990s. Those conditions ameliorated in the late 1990s and extend into the early 2000s so that coho salmon marine survival improved. Such fluctuations have occurred in the past as variable cycles but future cycles would likely be within the context of global warming, which would likely prohibit predictions from past conditions (Lawson 2005).

Recently, NMFS (2016c) conducted a 5-year status review of Oregon Coast coho, concluding that there have been positive improvements to the Oregon Coast ESU including long-term abundance trends and escapement due, in part, to reduced harvest and hatchery releases coupled with high marine survival. In the Umpqua Stratum (defined by the Oregon and Northern California Coasts Technical Recovery Team to evaluate population recovery) that includes coho in the South Umpqua Sub-basin, there have been numerous efforts to acquire and restore conditions in watersheds including placement of large wood, road maintenance, improvements in fish passage, riparian plantings, and culvert replacements that reduce habitat degradations caused by human use and development (NMFS 2016c). In the Mid-South Coast Stratum, which includes coho in the Coos and Coquille sub-basins, there have been multiple projects similar to those in the Umpqua Stratum, as well as side channel reconnections implemented through watershed councils. In both strata, issues of continuing loss of beavers with concomitant loss of coho salmon rearing habitat, primary productivity, nutrient retention/cycling, floodplain connectivity, fish passage, and stream flow moderation remain ongoing habitat concerns for Oregon Coast coho (NMFS 2016c).

Compared to the Oregon Coast ESU as a whole, the proportion of escapements by coho salmon produced in hatcheries to wild spawners has been quite low in the Umpqua, Coos, and Coquille Rivers (Table 71 in Lawson 2005), though correct identification of hatchery and wild fish has been an issue in such surveys. As noted above, decreasing the proportion of hatchery spawners benefits wild stock.

NMFS (1996) developed an approach and criteria for evaluating human-related effects to anadromous salmonid habitats which focuses on the following six pathways of potential impact: 1) water quality, 2) habitat access, 3) habitat elements, 4) channel condition and dynamics, 5) flow/hydrology, and 6) watershed condition. BLM and Forest Service developed watershed analyses, in part to meet requirements of their respective land management plans, specifically to comply with the objectives of the ACS in the NWFP. In addition to federal agencies, watershed assessments have been developed by local watershed councils and Oregon's natural resource agencies and are available through the Oregon Watershed Enhancement Board. Watershed assessments provide evaluations of fish habitats and water quality and describe how natural process and human activities are affecting those resources (Governor's Watershed Enhancement Board 1999). Available watershed analyses developed by these sources are listed in table 3.5.4-1 for the fifth-field watersheds crossed by the Pipeline.

Summaries for three of the watershed analyses are provided in appendix B.3 to PCGP's Resource Report 3 (table B.3-1a through table B.3-1g). As a rule, streams lacked in-stream LWD, fish access was limited, sedimentation was excessive, and habitats had been affected by high flows that degraded in-stream habitats. NMFS' (2016c) review of habitat conditions within the range of the Oregon Coast coho ESU and the Coos, Coquille, and South Umpqua subbasins was discussed, above. The updated status review indicates that there has been improvement in the biological status of Oregon Coast coho in the last five years but factors related to persistence of coho in the ESU have not significantly changed since the former status review conducted in 2012 (NMFS 2016c).

TABLE 3.5.4-1

Watershed Assessments Conducted by Federal and State Agencies for 5th Field Watersheds Crossed by the Pipeline

Sub-basins and Fifth Field Watersheds	Watershed Analysis, BLM and/or Forest Service	Watershed Assessment, Oregon Watershed Enhancement Board
Coos Sub-basin		
Coos Bay-Frontal Pacific Ocean	● Catching-Beaver Watershed Analysis (BLM 2010)	● Coos Bay Lowland Assessment and Restoration Plan (Coos Watershed Association 2006) ● Catching Slough, Daniel's Creek and Heads of Tide Sub-basin Assessment and Restoration Opportunities (Coos Watershed Association 2008)
Coquille Sub-basin

East Fork Coquille River	● East Fork Coquille Watershed Analysis (BLM 2000)	
Middle Fork Coquille River	● Upper Middle Fork Coquille Watershed Analysis (BLM, 1999a) ● Middle Fork Coquille Watershed Analysis (BLM 2007)	
South Umpqua Sub-basin		
Olalla Creek-Lookingglass Creek	● Olalla-Lookingglass Watershed Analysis (BLM 1999b)	● Olalla/Lookingglass Watershed Assessment and Action Plan (DeVore and Geyer 2003).
Clark Branch-South Umpaqua River	● Middle South Umpqua Watershed Analysis (BLM 1999c)	● Middle South Umpqua Watershed Assessment and Action Plan (Geyer 2003a).
Myrtle Creek	● Myrtle Creek Watershed Analysis and Water Quality Restoration Plan (BLM 2002)	● Myrtle Creek Watershed Assessment and Action Plan (Geyer 2003b)
Days Creek-South Umpqua River	● South Umpqua Watershed Analysis and Water Quality Restoration Plan (BLM 2001b)	● South Umpqua River Watershed Assessment and Action Plan (Geyer 2003c)
Upper Cow Creek	● Cow Creek Watershed Analysis. (Forest Service 1995)	● Upper Cow Creek Watershed Assessment and Action Plan (Geyer 2003d)
Little Butte Creek	● Little Butte Creek Watershed Analysis (BLM and Forest Service 1997b).	● Little Butte Creek Watershed Assessment (Little Butte Creek Watershed Council 2003)

BLM and/or the Forest Service evaluated habitat conditions in the ten 5th field watersheds crossed by the Pipeline; most of the evaluations were conducted around 2000 (see table 3.5.4-1). More recently, various watershed associations, Native American tribes, and/or watershed councils conducted new assessments listed in table 3.5.4-1, including the Umpqua Basin Watershed Council (authored by Geyer 2003). The watershed assessment of the larger South Umpqua Sub-basin (HUC 17100302) included the Days Creek–South Umpqua River and Elk Creek watersheds. These more recent watershed assessments use ODFW Aquatic Inventory and Analysis data, which were also summarized below in table 3.5.4-10a and table 3.5.4-10b.

Species Recovery

NMFS (2016b) released a final recovery plan that addressed limiting factors and threats to each coho population within the Oregon Coast ESU including those within the Coos, Coquille, and

Umpqua River systems. Primary limiting factors in the Coos and Coquille populations include stream complexity with water quality the secondary limiting factor. In the South Umpqua population, the primary limiting factor is water quantity with stream complexity and water quality as secondary limiting factors.

Among other actions, the plan calls for protection and restoration of tidally influenced habitats in the Coos estuary by reconnecting intertidal wetlands and tidal channels by removing dikes, levees, and tidegates. The plan also calls for monitoring predation by non-native fish in the Coquille and Coos River and reducing populations of predaceous non-native species in the Coquille River. Recovery of Oregon Coast coho in those two population areas is also dependent on improving riparian forests to increase shade and reduce stream temperatures and improve water quality. Additionally, the plan directs increased habitat complexity that would restore winter habitat refuge areas in the floodplains in freshwater ecotones of upper tidal areas of the Coos estuary.

Key recovery strategies and potential actions that would improve coho populations and habitats in the Mid-South Coast Stratum, including the Coos and Coquille populations include: improvement of riparian conditions on state and private timber lands, improve water quality on rural (residential and agricultural) lands, maintain the aquatic conservation strategy on federal lands, manage beavers to increase habitats associated with beaver ponds and dams, restore estuary and tidal lands, evaluate instream flows with focus on connectivity, water temperatures, and riparian protections to support salmon.

The recovery plan also addresses predation on Oregon Coast coho by non-native smallmouth bass and largemouth bass in the South Umpqua population. Recovery of the South Umpqua population is also dependent on restoration of watershed processes that promote winter and summer rearing habitats (e.g., wood recruitment, habitat complexity, floodplain connectivity). Key recovery strategies and potential actions that would improve coho populations and habitats in the Umpqua Stratum, including the South Umpqua population includes: evaluate instream flows with focus on connectivity, water temperatures, and riparian protections to support salmon, improvement of riparian conditions on state and private timber lands, improve water quality on rural (residential and agricultural) lands, maintain the aquatic conservation strategy on federal lands, manage beavers to increase habitats associated with beaver ponds and dams, and improve fish passage at dams, culverts and other identified barriers.

Life History, Habitat Requirements, and Distribution

Miller and Sadro (2003) found that approximately one-half of each brood of coastal coho salmon in Winchester Creek/South Slough (which empties into Coos Bay approximately 5 miles south of the LNG Terminal) in 1999 and 2000 moved to the estuary as sub-yearlings (age 0). A portion of these juveniles lived in the ecotone between freshwater and saline portions of the estuary for up to 8 months and then moved back upstream to overwinter. Fish that moved to the ecotone in fall and winter had a mean residency of 48 days in 1999 and 64 days in 2000. Some of these fish resided in an off-channel beaver pond. In spring, age 1 smolts had a mean residence time in the ecotone of only 18 days and a mean residence time in the estuary of 5.8 days. Coastal coho salmon smolts would not be expected to utilize the more saline waters near the LNG Terminal area for the extended periods of time as they were shown to reside in the ecotone.

Radiotelemetry studies conducted by Oregon State University researchers (Schreck et al. 2002) in the Nehalem River estuary indicate that coho salmon smolts spend about 2 weeks in the estuary before moving into the ocean. Fish monitoring in Tillamook Bay (approximately 170 miles to the north) indicated that coho salmon smolts (age 1+) were rarely found in shallow edge habitat during their residency period in the bay (Ellis 1999, 2002a, 2002b). Most of the yearling smolts appear to move quickly through the estuarine environment to the ocean. ODFW seining surveys conducted at the McCullough Bridge and Trestle sampling sites in summer 2005 and 2006 did capture juvenile coho salmon (ODFW 2006c), but coho salmon smolts are not expected to rear within the estuarine analysis area in the estuary for significant periods of time. Coho salmon smolts resided in the stream-estuary ecotone of South Slough for a range of 12 to 40 days (Miller and Sadro 2003).

Figure 3.5.4-1 provides the typical timing of use for coho salmon in the estuarine analysis area and riverine analysis areas. Within the estuary, some coho salmon rearing occurs but most juvenile use is during migration to the ocean (Gray 2007). During the period between October 1 and February 15 when all in-water construction would occur, juvenile coho salmon in the estuary and lower Coos River are likely to be absent but adult coho salmon would be holding and/or migrating upstream (see figure 3.5.4-1).

Life stage requirements of coho salmon within freshwater habitats in the Oregon Coast ESU are expected to be similar to those described above for coho salmon in the SONCC ESU (see section 3.5.3.1). Within the entire ESU, adults generally enter coastal streams in the fall and spawn from November through possibly March. Peak spawning is during December or January (NMFS 2004). After hatching in spring, parr inhabit areas of slow flows and spend a second winter in freshwater before outmigration to the ocean as smolts, generally March through June (NMFS 2004).

Specific timings of life history phases for Oregon Coast coho salmon are shown in figure 3.5.4-1 within the in-stream portion of the Pipeline project area are available for individual rivers or tributaries in the vicinity of waterbodies crossed by the Pipeline. Smolt outmigration in the Umpqua River mainstem and tributaries lasts from March through June, with peak outmigration from April through mid-May. Similarly, peak outmigration in the Coquille River is from late March to early May, although the duration of outmigration is shown in figure 3.5.4-1 to extend from mid-February to mid-June.

Peak timing of river entry by adults to the Umpqua, Coos, and Coquille is early to mid-October although adults begin entrance to all three drainages in early September through January. Spawning in the Umpqua River begins in early October, and lasts through January, peaking in November and December (see figure 3.5.4-1). Though not shown in figure 3.5.4-1, spawning in the Coos River lasts from mid-November through late January, peaking in mid-December as well as in the Coquille River though spawning there lasts from mid-November through early February (Weitkamp et al. 1995, see Appendix Table C-4). In-stream construction within tributaries to the Coos, Coquille, and South Umpqua Rivers and within range of the Oregon Coast ESU would be from July 1 through September 15. Coho salmon adult upstream migration would be occurring during the end of the in-stream construction window but spawning would not yet have started. Incubation and fry emergence from gravel, juvenile fry rearing and juvenile smolt out-migration would not be occurring between July 1 and September 15 (see figure 3.5.4-1).

Based on genetic data and recoveries of tagged fish, the Oregon Coast coho ESU extends to Pacific Ocean tributaries from Cape Blanco north to the Columbia River. Coho in the ESU inhabit waterbodies in the following nine fifth-field watersheds that would be crossed by the Pipeline: Coos Bay-Frontal Pacific Ocean (HUC 1710030403), North Fork Coquille River (1710030504), East Fork Coquille River (HUC 1710030503), Middle Fork Coquille River (HUC 1710030501), Olalla Creek-Lookingglass Creek (HUC 1710030212), Clark Branch-South Umpqua River (HUC 1710030211), Myrtle Creek (HUC 1710030210), Days Creek-South Umpqua River (HUC 1710030205), and Upper Cow Creek (HUC 1710030206). Table 3.5.4-2 summarizes the number of waterbodies crossed within the Pipeline project area that are known or assumed to support Oregon Coast coho.

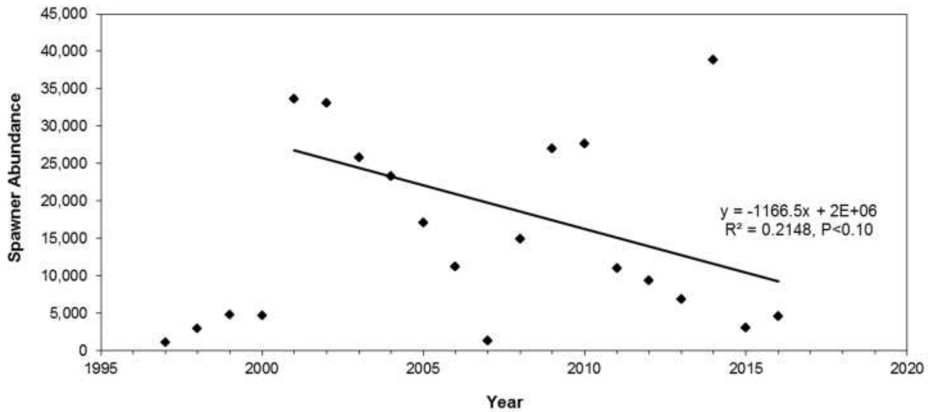
Population Status

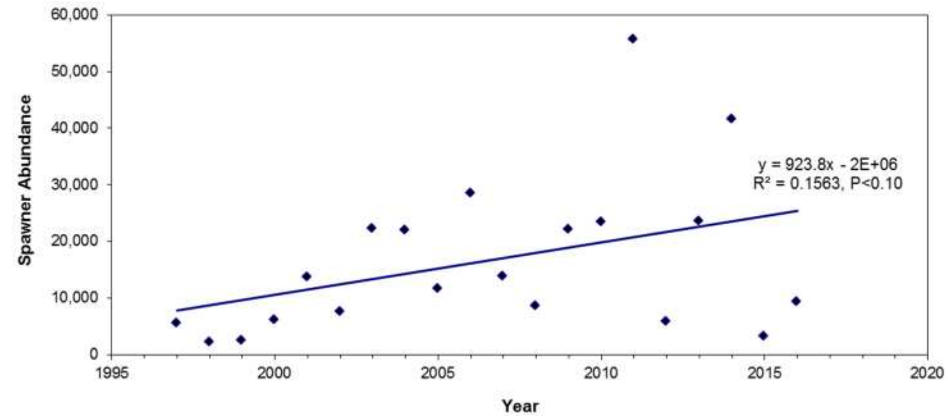
Abundance of naturally producing coho within the Coos Subbasin peaked at 33,595 spawners in 2001 but has generally diminished since then to 11,000 spawners in 2011 and to 9,400 in 2012; the declining trend in spawner abundance since 2001 is significant (see figure 3.5.4-2A).

Coho spawner abundance in the Coquille Subbasin (see figure 3.5.4-2B) and South Umpqua Subbasin (see figure 3.5.4-2C) had both been increasing at significant rates between 1997 and 2011 but declined dramatically in 2012, through 2016, the fewest wild spawners since 2008 in the South Umpqua during 2016 and fewest since 1999 in the Coquille Subbasin during 2015. The overall trend in total number of spawners in all three subbasins, combined (see figure 3.5.4-2D) had likewise been increasing through 2011 but numbers of spawners in 2012 were the fewest since 2000 in the riverine analysis area for Oregon Coast coho salmon. Although the increasing trend through 2011 and decline in 2012 was apparent in all populations of the Oregon Coast ESU (ODFW 2013b), the low spawner abundance since 2012 indicates there has been considerable variation but no overall trend, from 1997 through 2016 in the Oregon Coast ESU, similar to that shown in figure 3.5.4-2D.

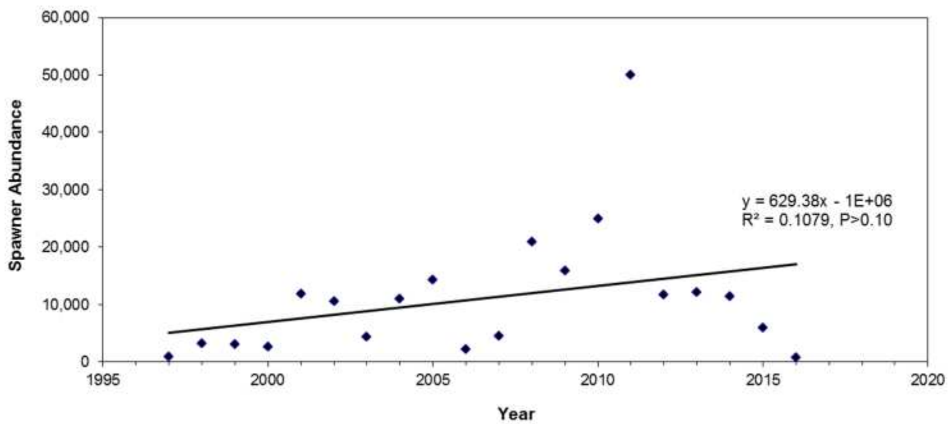
During the 20th century, there had been a prolonged decline in numbers of recruits per spawner (Weikamp et al. 1995; Good et al. 2005) wherein recruits from the return years 1997–1999 failed to replace parental spawners. Since 2000, increased marine survival rates and higher rainfall have likely contributed to a recent upswing in recruits (NMFS 2011d; Stout et al. 2012). But that trend was interrupted during return years 2005, 2006, and 2007 as recruits again failed to replace parental spawners. Possible explanations for recent recruitment failures include the possibility that higher spawning abundance levels in recent years had reached the current carrying capacity of the degraded freshwater environment.



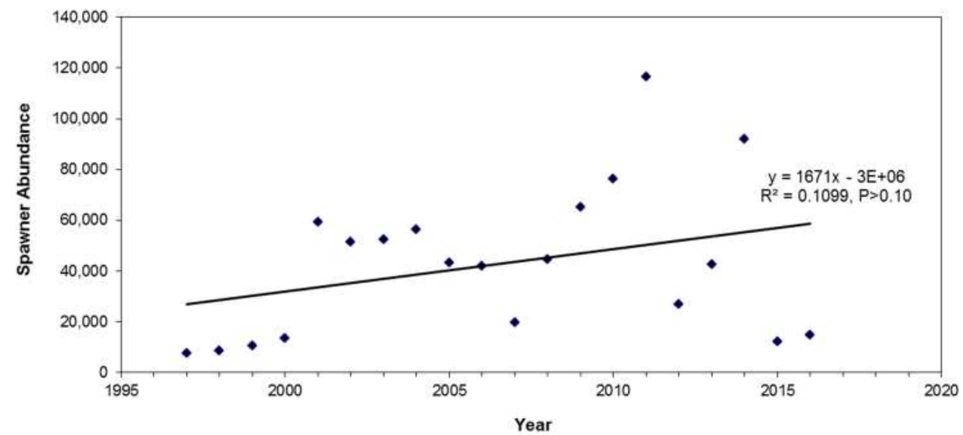
A. Coos Subbasin



B. Coquille Subbasin



C. South Umpqua Subbasin



D. All Subbasins in Analysis Area

Figure 3.5.4-2 Estimated Abundance of Wild Adult Coho Spawners in the Oregon Coast Coho ESU 1997 to 2016, within Three Subbasins Crossed by the Pipeline Project (Source: ODFW 2017d)

As total spawning abundance has been at highest levels since the 1950s, the total numbers of recruits remain lower than in the 1950s–1970s (NMFS 2011d; Stout et al. 2012). These possibilities indicate that degraded freshwater habitat conditions may limit the Oregon Coast coho ESU from rebounding from another prolonged period of poor marine survival of recruits, should that occur in the future. The possibility that either of these factors, individually or together, contributed to the extreme population declines observed in 2012 has not been reported.

Critical Habitat

Critical habitat for the Oregon Coast coho salmon ESU was first proposed in May 1999 (NMFS 1999c). Proposed critical habitat included all river reaches accessible to Oregon Coast coho salmon ESU which were listed as threatened at the time (see discussion above). Proposed critical habitat consisted of water, substrate, and adjacent riparian zones of estuaries and rivers including those in the Umpqua (HUC 17100302), Coos (HUC 17100304) and Coquille (HUC 17100305) hydrologic units (NMFS 1999c). Though not specifically identified, the Coos Bay estuary would have been included. The 1999 proposal was terminated when the District Court set aside the 1998 final rule determining threatened status for the Oregon Coast ESU (see discussion above).

Following re-proposing Oregon Coast coho salmon ESU for listing as threatened in June 2004, critical habitat for the ESU was likewise re-proposed in December 2004 (NMFS 2004). More recently critical habitat has been designated (NMFS 2008d) in three critical habitat units that coincide with the Project components: Unit 9 – South Umpqua Subbasin (HUC 17100302) affected by the Pipeline; Unit 11 – Coos Subbasin (HUC 17100304 - includes the Coos Bay estuary) affected by the LNG Terminal and the Pipeline; and Unit 12 – Coquille Subbasin (HUC 17100305) affected by the Pipeline.

Similar to critical habitat designated for coho salmon in the SONCC ESU, critical habitat for Oregon Coast coho includes stream channels to an extent laterally to the ordinary high water mark (OHWM) (or bankfull elevation or bankfull width). NMFS also defined critical habitat in estuarine and nearshore marine zones as areas contiguous with the shoreline from the extreme high water mark out to a depth no greater than 30 meters (98 feet) below the mean low water mark (NMFS 2004).

Within these areas, NMFS (2004) identified PCEs of critical habitat that include sites essential to support one or more coho life stages (spawning, rearing, migration, and foraging). Those sites each are associated with physical and biological features essential coho conservations (e.g., spawning gravels, water quality, water quantity, side channels, and food base). The following are PCEs for designated critical habitat for the Oregon Coast coho (NMFS 2008d):

1. Freshwater spawning sites with water quantity and quality conditions and substrate supporting spawning, incubation, and larval development.
2. Freshwater rearing sites with water quantity and floodplain connectivity to form and maintain physical habitat conditions and support juvenile growth and mobility; water quality and forage supporting juvenile development; and natural cover such as shade, submerged and overhanging large wood, log jams and beaver dams, aquatic vegetation, large rocks and boulders, side channels, and undercut banks.
3. Freshwater migration corridors free of obstruction with water quantity and quality conditions and natural cover such as submerged and overhanging large wood, aquatic vegetation, large rocks and boulders, side channels, and undercut banks a) supporting juvenile and adult mobility and survival, b) supporting juvenile use of various of habitats that allow them to avoid high flows, avoid predators, successfully compete, begin the behavioral and physiological changes needed for life in the ocean, and ability to reach the

ocean, and c) essential for nonfeeding adults to successfully swim upstream, avoid predators, and reach spawning areas on limited energy stores.

4. Estuarine areas free of obstruction with water quality, water quantity, and salinity conditions supporting juvenile and adult physiological transitions between fresh- and saltwater; natural cover such as submerged and overhanging large wood, aquatic vegetation, large rocks and boulders, and side channels; and juvenile and adult forage, including aquatic invertebrates and fishes, supporting growth and maturation.
5. Nearshore marine areas free of obstruction with water quality and quantity conditions and forage, including aquatic invertebrates and fishes, supporting growth and maturation; and natural cover such as submerged and overhanging large wood, aquatic vegetation, large rocks and boulders, and side channels.
6. Offshore marine areas with water quality conditions and forage, including aquatic invertebrates and fishes, supporting growth and maturation.

Designated critical habitat for the Oregon Coast coho does not include unoccupied areas. The lateral extent of critical was defined as the width of the stream channel defined as the ordinary high-water line (NMFS 2008d). Human actions on land outside of the stream channel can modify or degrade physical and biological features of the stream and associated PCE at the site and/or in downstream reaches of designated critical habitat.

3.5.4.2 Environmental Baseline

Analysis Area

There are three action area components that are applicable to coho salmon in the Oregon Coast coho salmon ESU: the marine analysis area, the estuarine analysis area, and the riverine analysis area.

The marine analysis area extends approximately 12 nmi offshore to the continental shelf (see figure 2.1.1-2, under section 2.1.1). Within this analysis area, effects to coho salmon within coastal marine waters would be associated with LNG carriers entering and exiting the Port of Coos Bay from the Pacific Ocean that are assumed to transit the marine analysis area perpendicularly—east and west—as they approach and depart from Coos Bay (see the discussion above under section 3.2.1.2 for blue whales).

The estuarine analysis area was described above for marbled murrelet (see figure 2.1.1-2). The estuarine analysis area includes: 1) the existing Federal Navigation Channel which forms part of the waterway for LNG carrier traffic to and from the LNG Terminal, 2) the proposed access channel to the terminal slip, 3) the Navigation Reliability Improvements, 4) the area of North Slough adjacent to the Trans Pacific Parkway/U.S. Highway 101 (US-101) Intersection Widening, 5) the Eelgrass Mitigation site, 6) the Kentuck Project site and sites temporarily occupied during construction activities (see figure 2.1.1-2), and 7) the HDDs of Coos Bay estuary and Coos River.

The riverine analysis area is similar to that described above for coho salmon in the SONCC ESU. The riverine analysis area includes two components: 1) the water column and substrate of all waterbodies crossed by the Pipeline from the point of crossing to the extent downstream where water quality is affected by turbidity generated during construction and sediment generated by runoff from the construction right-of-way, and 2) waterbodies' associated riparian zones affected in the short-term during construction and in the long-term by operation. For coho salmon in the Oregon Coast ESU, the riverine analysis area is limited to fresh waterbodies within Coos Subbasin (HUC 17100304 – figure 3.5.4-3A), Coquille Subbasin (HUC 17100305 – figure 3.5.4-3B) and South Umpqua Subbasin (HUC 17100302 – figure 3.5.4-3C); see table 3.5.4-3.

Upper Cow Creek	1710030206		5	6		11
	TOTAL	**3**	**55**	**83**	**3**	**144**

a/ includes waterbodies crossed and waterbodies not crossed but immediately adjacent to the pipeline and within the right-of-way.
b/ includes stock ponds, industrial ponds.
c/ The Coos River is influenced by tides but it is included as a perennial waterbody in this watershed.
d/ Elk Creek Watershed would be crossed but no waterbodies would be affected within the watershed.

The downstream extent of the riverine analysis area was determined by estimating the likely distance downstream that suspended sediment concentrations generated during stream crossings could attenuate to ambient background levels within the Pipeline project area. The methods used to estimate this distance are explained below.

Pipeline project TSS concentrations generated during wet open-cut pipeline construction have been estimated from models developed by Reid et al. (2004). Amounts of TSS produced during dry open-cut construction (fluming, dam-and-pump) adjustments are fractions of the concentrations produced during wet-open cuts (Reid et al. 2004). Estimates of TSS produced during dry open-cut construction across waterbodies in fifth-field watersheds are presented below in section 3.5.4.3. Average sediment percentages (grain sizes including gravel, sand, silt, and organics) for streams within each fifth-field watershed (see table 3.5.4-10a and table 3.5.4-10b below in this section and table 3.5.4-17 in section 3.5.4.3) were assumed as fractions of the TSS generated during construction and concentrations of each grain class at various distances downstream were estimated using a simple sediment transport model (Ritter 1984). Downstream settling distances would be much greater for deeper waterbodies with high flow velocities than for shallow, slow flowing streams.

Using models noted above and data on the average sediment composition, stream depth, and average summer low flows for streams within range of Oregon Coast coho that would be crossed by the Pipeline, the average downstream distance expected to near a concentration of 2 mg/l for silt (0.0016 cm diameter, 0.023 cm/sec settling velocity) ranges from 34 meters (112 feet) in the Coos Bay Watershed to 482 meters (1,581 feet) in the Upper Cow Creek Watershed; the average downstream distance expected to near a concentration of 2 mg/l for clay (0.0004 cm diameter, 0.0014 cm/sec settling velocity) ranges from 595 meters (1,952 feet) in the Coos Bay Watershed to 7,315 meters (23,993 feet) in the Upper Cow Creek Watershed. These estimates are for average summer low flows likely to occur during construction within the ODFW (2008) allowed in-stream construction period.

While distances for fine clay settling to 2 mg/l would vary among sites, meaningful changes in suspended sediment concentrations at all sites should be much less than average distances of the estimated fine clay particle sizes downstream distance at average low summer flows. The estimated average downstream distance traveled of these very fine particles is a reasonable conservative limit to consider for the analysis area. The riverine analysis area used in this BA for Oregon Coast coho salmon has been limited to downstream distances ranging from 1,952 feet to 23,993 feet (0.4 mile to 4.5 miles) within the affected fifth-field watersheds in the range of Oregon Coast coho salmon (see figure 3.5.4-3).

Species Presence

Based on genetic data and recoveries of tagged fish, the Oregon Coast coho ESU extends to Pacific Ocean tributaries from Cape Blanco north to the Columbia River. Coho in the ESU inhabit waterbodies in 10 fifth-field watersheds that would be crossed by the Pipeline. An eleventh, the Elk Creek Watershed (HUC1710030204), would be crossed but no waterbodies would be affected within the watershed. The Pipeline would cross the following that are inhabited by Oregon Coast coho: Coos Bay-Frontal Pacific Ocean (HUC 1710030403), North Fork Coquille River (1710030504), East Fork Coquille River (HUC 1710030503), Middle Fork Coquille River (HUC 1710030501), Olalla Creek-Lookingglass Creek (HUC 1710030212), Clark Branch-South Umpqua River (HUC 1710030211), Myrtle Creek (HUC 1710030210), Days Creek-South Umpqua River (HUC 1710030205), and Upper Cow Creek (HUC 1710030206). Upstream migrations by coho in the Middle Fork Coquille River are blocked (Bradford Falls) at River Mile 27.3, about 5.3 miles southwest of Camas Valley, Oregon.

The Pipeline would actually cross 116 of the waterbodies in table 3.5.4-4, 111 of them by dry open cutting (flume or dam-and-pump), while the South Umpqua River would be crossed twice, once by a DP crossing at MP 71.27 and again by a diverted open cut at MP 94.73. Coos Bay would be crossed by two HDDs, one from MP 0.28 to MP 1.00, the other from MP 1.46 to MP 3.02. The Coos River (a reach of the estuary but categorized as a perennial waterbody) would be crossed using HDD at MP 11.13. Twenty-eight of the waterbodies listed in table 3.5.4-4 would not be crossed by the Pipeline but are adjacent to the centerline. Blasting may be necessary to construct across 22 streams that would be crossed by dry open cut methods (see Project Description) because the streambed of each is bedrock (see table 3.5.4-4).

All affected waterbodies within the three subbasins and nine fifth-field watersheds (Elk Creek HUC 1710030204, is crossed but no waterbodies are affected) that are within the range of Oregon Coast coho salmon ESU proximate to the Pipeline are included in table 3.5.4-4. There are 144 waterbodies included in the table, of which 55 are perennial, 83 are intermittent, one is an estuary (crossed twice), and three others are ponds. Coho salmon are known to occur in 31 of the waterbodies and are assumed to be present in 12 others based on connectivity to perennial streams known to support coho salmon, the presence of steelhead and/or resident salmonids, and/or information provided by fisheries biologists. Data in table 3.5.4-4 were revised based on ODFW (2017f) fish habitat distribution shapefiles and Oregon Department of Forestry (ODF 2018) Forest Practices statewide hydrography shapefiles that provide field evaluations for fish presence/absence in stream segments.

a/ Dry open cut crossing methods include flume or dam-and-pump procedures. Dam-and-pump methods would be utilized where streambed blasting is anticipated to eliminate blasting around the flume. The dam-and-pump crossing method is the preferred crossing procedure in steep incised drainage valleys where worker safety may be compromised when placing ("threading") the pipe string under the flume pipe and where there is a risk of upsetting the flume during this operation. The dam-and-pump crossing method is also the preferred crossing method on small streams under low flow conditions during the recommended ODFW-recommended in-water work period. PCGP proposes temporary/short-term fish passage restriction when completing dam-and-pump crossings within the ODFW-recommended in-water work period. Appendix M provides details of stream crossings.

b/ ODFW 2017f; ODF 2018

c/ Assumes fisheries construction windows only apply to those waterbodies flowing at the time of construction and windows do not apply to HDD crossings.

d/ Steambed bedrock based on PCGP's Wetland and Waterbody delineation surveys. Streambed bedrock may require special construction techniques to ensure pipeline design depth. Special construction techniques may include rock hammering, drilling and hammering, or blasting. The need for blasting would be determined by the construction contractor and would only be initiated after ODFW blasting permits are obtained.

In-stream construction of the Pipeline will occur before most Oregon Coast coho begin upstream migration and spawning by adults (see figure 3.5.4-1). However, juvenile coho are expected to be rearing in many of those streams. Although there are no data on numbers of juveniles expected to be present in streams crossed by the Pipeline, the following estimation procedure was developed after an estimate for numbers of juveniles present in streams crossed was requested by NMFS (2015e).

Total stream miles occupied by coho salmon within the 4th Field HUCs in table 3.5.4-5 and each of the 5th Field HUCs crossed by the Pipeline were derived with GIS by combining shapefiles of ODFW Fish Distribution data (ODFW 2017f) with watershed shapefiles from National Hydrography Dataset (USGS 2016). Stream miles with coho spawning habitats and coho rearing habitat in the range of Oregon Coast coho were similarly derived; stream miles in those habitats were added to provide Stream Miles for Juveniles' Presence in table 3.5.4-5.

Numbers of redds and spawning adult coho salmon counted in fourth field watersheds over time are available on the StreamNet (2012) Database accessed through the ODFW Natural Resources Information Management Program. The database provided only 15 records of redd surveys for Oregon Coast coho in the South Coast 4th Field HUC, all limited to streams within the South Umpqua River (HUC 17100302). The surveys were conducted during 1991 and 1992. With so few records available, numbers of adult coho salmon (not including jacks or subadults) reported as peak live or dead fish were used to estimate numbers of juvenile fry present in streams that would be crossed by the Pipeline. Data for numbers of adults counted per mile from StreamNet Database are summarized in table 3.5.4-6.

TABLE 3.5.4-6

Summary of Records a/ for Spawning Adult Coho Within the Oregon Coast ESU in 4th Field Watersheds (HUCs) Crossed by the Pipeline Project

Subbasin	Number of Surveys	Year(s)	Average Adults (Live and Dead) per Mile Surveyed	90% Confidence Interval
Coos	706	1950 to 2010	87.58	± 8.01
Coquille	474	1950 to 2010	24.51	± 2.64
South Umpqua	153	1981 to 2004	3.47	± 0.85

Source: StreamNet 2012.

The following assumptions have been applied to the adult spawning data in each of the three watersheds coinciding with Oregon Coast coho and proposed for crossing by the Pipeline:

- The male:female ratio of live or dead spawners is 1:1 (Knudsen et al. 2003),
- At low to moderate densities of spawners, there is 1 redd for each female (Lestelle and Weller 2002);
- Redds are only present in stream reaches classified as spawning habitat by ODFW (2014);
- The average number of eggs per redd is between 300 and 1,200 with 800-900 eggs being most frequent (Sandercock 1991)
- Under average conditions, 15-27 percent of all eggs will survive during incubation (mean

of 27.1 percent survival was observed in Oregon coastal streams Sandercock 1991);

- Juveniles utilize spawning habitats during rearing as well as rearing habitats as classified by ODFW (2014c). Juveniles distribute themselves in uniformly spaced territories regardless of presence of pools, riffles or runs in the natal stream.

With these assumptions, the following are estimates of coho redd abundances in subbasins:

- Average 43.79 redds per mile (± 4.01 redds per mile) within all spawning habitats in the Coos River 4th Field HUC;
- Average 12.26 redds per mile (± 1.32 redds per mile) within all spawning habitats in the Coquille River 4th Field HUC;
- Average 1.74 redds per mile (± 0.43 redds per mile) within all spawning habitats in the South Umpqua River 4th Field HUC;

Average values for redds per mile in 4th Field HUCs, stream miles of spawning and rearing habitats in HUCs, and the assumptions above for eggs per redd and egg survival rates were used to estimate Juveniles per Mile of Habitat in table 3.5.4-5 for each of the 5th Field HUCs crossed within range of the Oregon Coast ESU. Values for redds per mile within 90% confidence intervals were not carried through the analyses in table 3.5.4-7. In reality, estimates of Juvenile Fry per Mile of Habitat would vary from year to year showing at least as much variability as the estimated abundance of wild adult coho spawners reported within the three subbasins of the analysis area from 1997 to 2016, shown in figure 3.5.4-2 above.

There would be some natural mortality between juvenile fry and juvenile smolt stages and during the period from fry emergence (through the end of May) before pipeline construction (beginning July 1). Therefore, estimates are very conservative. Waterbodies within the Coos, Coquille, and South Umpqua subbasins would be crossed between July 1 and September 15. Based on figure 3.5.4-1, instream construction would likely avoid the juvenile coho out-migration periods during June; there would be few or no post-winter pre-smolt juvenile coho present during construction. Very few are expected because reported over-winter survival rates of juvenile coho are <40 percent, at least in waterbodies studied within the Coos Bay Frontal-Pacific Ocean 5th field watershed (Weybright and Giannico 2017).

TABLE 3.5.4-7

Estimates of Juvenil Fry Coho in the Oregon Coast ESU Present in 4th Field and 5th Field Watersheds Crossed by the Pipeline Project

Subbasin and Fifth-Field Watersheds	Total Redds in HUC a/	Total Eggs in HUC b/	Total Juvenile Fry Surviving in HUC c/	Juvenile Fry per Mile of Habitat d/

Days Creek-South Umpqua River	123	104,776	28,394	285
Upper Cow Creek	0	0	0	0

a/ Total Redds in HUC = the Average Redds per Mile in 4th Field HUC multiplied by Stream Miles of Spawning Habitat in table 3.5.4-5.
b/ Total Eggs in HUC = average of 850 eggs per red (see assumptions) multiplied by Total Redds in HUC.
c/ Total Juvenile Fry Surviving in HUC = 27.1 percent average survival rate of eggs (see assumptions in text) multiplied by Total Eggs in HUC.
d/ Juvenile Fry per Mile of Habitat = Total Juvenile Fry Surviving in HUC divided by Stream Miles of Juvenile's Presence in table 3.5.4-5.

Habitat

Estuarine Habitats

The estuarine habitat along the pipeline route is located in mostly shallow regions of Coos Bay and in the Coos River. Tidally influenced waters extend over seven miles upstream in Catching Slough and Coos River. Tidal gates at the mouths of Kentuck Slough and Willanch Slough have changed salt water inundation and flow regimes in the lower reaches of those waterbodies.

Substrates within the estuary include sub-tidal (continuously submerged) and intertidal (periodically submerged by tidal action) zones. Both zones support various habitats that have been classified by type of bottom material (including rock, sand, mud, and wood/organic debris) and relative position within the estuary (aquatic bed, shore, flat, beach/bar, and tidal marsh) by the ODLCD (1987). Sub-tidal and intertidal habitats within the Coos Bay estuary were mapped in 1987 as a pilot project for the ODLCD Coastal Management Program Dynamic Estuary Management Information System, or DEMIS (ODLCD 1998). The Pipeline route coincides with shallow intertidal and sub-tidal fine bottom and unconsolidated bottom habitat, with a few regions of mixed seabeds of eelgrass, attached algae, and tidal marsh.

Tidal mud flats and eelgrass beds are found on the west shore of Coos Bay; both habitats are utilized by most fish species within the bay at some time during the year (Cummings and Schwartz 1971). Eelgrass densities in Coos Bay are greatest at relatively shallow depths, slightly above and below the mean low water level (Thom et al. 2001). Distribution of eelgrass within the estuary has apparently changed slightly since 1987 (ODLCD 1998). Preliminary distribution of eelgrass (interpreted from infrared imagery, with some field verification) was evaluated in the vicinity of the project area during 2005 (Clinton 2007). Eelgrass on intertidal mud flats between Glasgow Point (Kentuck Inlet) and Russell Point (Haynes Inlet) decreased since 1987 while eelgrass beds on intertidal mud and mud/sand flats extending outward from Kentuck Inlet had apparently increased.

Natural turbidity in the estuary was judged to be higher at upper bay locations, away from water influx from the ocean (Moffatt & Nichol 2006). Turbidity (measured in NTUs) was evaluated at the Charleston Bridge, near the entrance to Coos Bay, and estimated as TSS (measured in mg/l) for modeling dredge-generated turbidity during construction of the proposed LNG Terminal (Moffatt & Nichol 2006). At that location, turbidity varied from 3.7 to 18.1 NTUs (5.7 to 45.7 mg/l) but sometimes exceeded 200 NTU.

Summaries of watershed health indicators have been reported by the Coos Watershed Association for tideland habitats accessible by Oregon Coast coho salmon (Oregon Watershed Enhancement Board 2007). Table 3.5.4-8 provides conditions in the following three estuarine zones:

Tidal wetlands: Marshes and swamps; a vegetated wetland that is periodically inundated by tidal waters. Tidal wetlands include emergent, scrub-shrub, and forested wetland types.

Tidal flat: An area inundated by all high tides and exposed only at low tide. Some tidal flats have extensive growth of algae or seagrass; others are bare mud.

Sub-tidal zone: Sub-tidal estuarine habitats include channel bottoms, slope bottoms, and the open water above them.

Wetland functions within the estuary have been affected by dikes, tide gates, roads and railroads, ditches, and dams that restrict tidal flows and/or have changed tidal flow patterns. Agricultural land uses have contributed to erosion of channels and, along with channel armoring, has affected vegetation diversity in wetlands, channel shading, and salmonid habitat function; tidal wetlands have also been affected excavations and disposal of dredged materials (Oregon Watershed Enhancement Board 2007).

TABLE 3.5.4-8

Watershed Health Indicators for Three Tidal Habitat Zones in the Coos Bay Estuary

Tideland Habitat Zone	Hydro-Modification	Sediment Regime	Water Quality	Vegetation Modification	Invasive Species	Habitat Loss
Tidal Wetlands	Limiting >40% historic wetlands modified	Limiting >40% wetlands affected by major change in sediment regime	Moderate DEQ water quality criteria met <90% of samples	Limiting 40% wetland vegetation altered by land use	Moderate Limited Invasive species impact on tidal wetland function	Limiting >40% zone with complete fill or conversion
Tidal Flat Zone	Limiting >40% historic tidal flats modified	Moderate 20-40% tidal flats affected by major change in sediment regime	Moderate DEQ water quality criteria met <90% of samples	N/A	Moderate Limited Invasive species impact on tidal flat function	Moderate 20-40% zone with complete fill or conversion
Sub-Tidal Zone	Moderate 20-40% historic zone modified	Moderate 20-40% sub-tidal zone affected by major change in sediment regime	Moderate DEQ water quality criteria met <90% of samples	N/A	Moderate Limited Invasive species impact on sub-tidal zone function	Moderate 20-40% zone with complete fill or conversion

NMFS performed a preliminary survey of benthic invertebrates in the vicinity of the Federal Navigation Channel in 1989 (Miller et al. 1990). The study characterized the macroinvertebrate community at 20 sites in and adjacent to the navigation channel in support of channel deepening in Coos Bay. There were 121 different invertebrate taxa identified with a mean density of 2,617 individuals/square meter (m^2). The highest invertebrate densities were observed in the lower bay, downstream from the LNG Terminal site (CM 2 to CM 5). One of the sites (Station 11) was located in the navigation channel, immediately adjacent to the LNG Terminal where 16 different taxa were identified and the mean density was 552 individuals/m^2. The polychaete worm, *Glycera tenuis*, dominated the taxa at this location (n=23). Nearby sampling stations also were found to support high numbers of polychaetes, including *Glycera tenuis* and *Heteropodarke heteromorpha*. *Corophium salmonis*, an amphipod important as juvenile salmonid prey, was rarely found in the study area. Total benthic invertebrate densities in Coos Bay ranged from 375 to 13,546/m^2 and were found to be lower than densities observed in the Umpqua River estuary (range from <200 to >50,000/m^2) and the Columbia River estuary (range from <1,000 to >60,000/m^2) (Bottom et al. 1985; Miller et al. 1989; Durkin and Emmett 1980).

Previous studies by ODFW have shown that benthic macroinvertebrates in Coos Bay may not comprise a major portion of the diet for juvenile salmonids. Stomach contents of wild Chinook salmon and hatchery coho salmon juveniles were analyzed from July to September 1980 (Nicholas and Lorz 1984). The survey was performed during the outmigration period for juvenile salmonids, when juveniles are expected to be abundant within the estuary. The major prey species consumed by juvenile Chinook salmon (in order of abundance) were Pacific sand lance (n=89), terrestrial insects (n=59), and decapods (e.g., crab zoea and shrimp larvae) (n=27) (Nicholas and Lorz 1984). Only five amphipods (likely *Corophium* spp.) were identified in 143 Chinook salmon stomach samples. However, amphipods were the major prey species identified in juvenile coho salmon stomach samples (n=105). Other prey species found included terrestrial insects (n=27) and Pacific sand lance (n=25). Previous studies in Coos Bay have found that *Corophium* spp. are abundant in intertidal areas and constitute an important diet element for juvenile Chinook salmon and striped bass (BLM 1971). Shallow water habitats near the LNG Terminal have been mapped as habitat for *Corophium* spp (Coos County Planning Department 1979).

Based on the presence of juvenile salmonids at nearby ODFW sampling sites, it is likely that juvenile coho and other fish species utilize the shallow water areas near the LNG Terminal for foraging during periods of the year. The shoreline has been mapped as potential habitat for the amphipod *Corophium* spp., which is considered an important prey species (Coos County Planning Department 1979) and was shown to be consumed in large numbers by coho salmon (Nicholas and Lorz 1984). Shanks et al. (2011) sampled zooplankton in Coos Bay near the LNG Terminal site. A variety of zooplankton were found to be present within the bay, with potential salmonid forage items such as copepod adults, lavaceans, harpacticoid copepods, and Daphnia noted in abundance.

However, benthic studies conducted by NMFS within and in the vicinity of the Federal Navigation Channel found that *Corophium salmonis* occurred in much lower densities than other Oregon estuaries (Miller et al. 1990; Bottom et al. 1985; Miller et al. 1989; Durkin and Emmett 1980). Based on site observations made in November 2006, it appears that shallower habitats at the LNG Terminal site contain a higher percentage of fine substrates, and thus could support a greater abundance of benthic macroinvertebrates than had been observed within the navigation channel, which is dominated by coarser sand.

Freshwater Habitats

Conditions of aquatic habitats within the fifth-field watersheds in the Coos, Coquille, and South Umpqua subbasins that would be crossed by the Pipeline were evaluated with data collected by

ODFW in their Aquatic Inventories Project (ODFW 2014c). In cooperation with other agencies, ODFW has conducted stream surveys throughout the state including streams within watersheds crossed by the Pipeline. .Four types of habitat information provide quantitative evaluations of the fish habitat condition within the various watersheds: 1) pool habitat condition, 2) riffle habitat condition, 3) shade conditions, 4) woody debris habitat condition, and 4) riparian habitat condition. ODFW (Foster et al. 2001) has developed benchmark criteria for each of these habitat conditions that would represent undesirable and desirable habitat conditions. The benchmarks are provided in table 3.5.4-9 along with the various aquatic habitat conditions to which they apply.

TABLE 3.5.4-9

Oregon Department of Fish and Wildlife Aquatic Inventory and Analysis Project Criteria for Aquatic Habitat Conditions and Benchmarks

Aquatic Habitat Condition	Benchmark Level for Condition	
	Undesirable	Desirable
Pools		
Pool Area (% total stream area)	<10	>35
Pool Frequency (channel widths between pools)	>20	5-8
Residual Pool Depth (meters [m])		
Small Streams (<7 m wide)	<0.2	>0.5
Medium Streams (≥7 m and <15 m width)		
Low Gradient (slope <3%)	<0.3	>0.6
High Gradient (slope >3%)	<0.5	>1.0
Large Streams (≥15 m width)	<0.8	>1.5
Complex Pools (pools with ≥3 LWD pieces / km of reach length)	<1	>2.5
Riffles		
Width/Depth Ratio (active channel based)		
East Side	>30	<10
West Side	>30	<15
Gravel (% area)	<15	≥35
Silt-Sand-Organics (% area)	>20	<10
Volcanic Parent Material	>15	<8
Sedimentary Parent Material	>20	<10
Channel Gradient <1.5%	>25	<12
Shade (Reach Average, Percent)		
Stream Width <12 m		
West Side	<60	>70
Northeast	<50	>60
Central-Southeast	<40	>50
Stream Width >12 m		
West Side	<50	>60
Northeast	<40	>50
Central-Southeast	<30	>40
Large Woody Debris		
Pieces/100m Stream Length	<10	>20
Volume (m^3)/100 m Stream Length	<20	>30
"Key" Pieces (>60 cm and 10 m long)/100 m	<1	>3
Riparian Conifers (30 m From Both Sides of Channel)		
Number >20 inches dbh/1,000 feet Stream Length	<150	>300
Number >35 inches dbh/1,000 feet Stream Length	<75	>200

Source: Foster et al. 2001

Benchmark conditions are not absolute but they provide a method for comparing values of key aquatic habitat components (Foster et al. 2001) that are used to establish baseline conditions within watersheds to be crossed by the Pipeline. Pools provide refuges for fish during high and low stream flows. Pools provide slow water habitats for adults and juveniles, provide over-wintering habitat for some fish species, provide habitat during periods of low summer flows, and pools associated with large wood provide habitat complexity.

Riffles provide spawning habitats for various salmonid species that construct nests or redds in gravels of various sizes, specific to salmonid species. Sand, silt, and organic debris can reduce suitability of spawning habitats by filling pores between gravel particles that are necessary for intergravel stream flows, availability of oxygen, and for development of embryos; high percentages of sand, silt, and organic material in riffles indicate poor conditions as spawning habitat.

Riparian trees provide shade over stream channels which reduce deleterious effects of high summer water temperatures. Roots of riparian vegetation stabilize stream banks, contribute to development of bank undercutting (thermal and hiding cover), limit erosion and sedimentation from stream banks, and provide LWD as an important component of the aquatic habitat. LWD, especially contributed by riparian conifers, provides cover for fish, physical habitat complexity that influences stream flows and channel diversity, and biological complexity as substrate for macroinvertebrate communities that provide food for salmonids during different life stages (Foster et al. 2001).

Data used to evaluate aquatic habitat conditions, reported by ODFW (2014c), are provided in appendix X for each stream reach included in the inventories and evaluations of benchmark conditions are summarized in tables 3.5.4-10a and 3.5.4-10b, below.

Coos Subbasin - HUC 17100304. Data available from the ODFW (2014c) Aquatic Inventories Project provided aquatic habitat conditions for 33 stream reaches within the Coos Bay-Frontal Pacific Ocean Fifth-Field Watershed (HUC 710030403) surveyed between 1992 and 1999. The sampled reaches were of first, second or third order (Strahler numbers 1, 2, 3) streams with active channel widths (bankfull widths) averaging 5.8 meters and active channel heights averaging 0.5 meter.

Desirable conditions for pool habitat in surveyed reaches ranged from only 11 percent for pool frequency to 35 percent for residual pool depth (see table 3.5.4-10a). In general, pool habitat conditions were undesirable or less than desirable (moderate) for most streams within the watershed. Riffle habitats were relatively abundant (68 percent of stream reach areas) but degraded by high levels of silt, sand and organic materials and width to depth ratios of sampled reaches tended to be high, indicative of relatively shallow wide stream channels that provide less suitable habitat than deep, narrow channels (see benchmarks in table 3.5.4-9).

Riparian conditions in streams surveyed within the Coos Bay Frontal-Pacific Ocean watershed are mostly undesirable. Trees in less than half of the reaches provide adequate shade of stream channels and the numbers of large conifer trees within surveyed riparian zones were undesirable; large conifers were absent in many of the surveyed reaches. It is not surprising that the amount of LWD, including key pieces (pieces of large wood ≥0.6 meter diameter and ≥12 meters long), is undesirable, less than benchmark. Low estimates of riparian shade is indicative of lower gradient streams and floodplains that have been altered by past land uses in the watershed. As one consequence, summer stream temperatures in lower reaches exceed levels suitable as juvenile salmonid summer rearing habitats (Coos Watershed Association 2006). The ODFW (2008) in-stream construction window for coastal tributaries is July 1 to September 15 although work in the Coos Bay estuary and Coos River mainstem is allowed from October 1 to February 15.

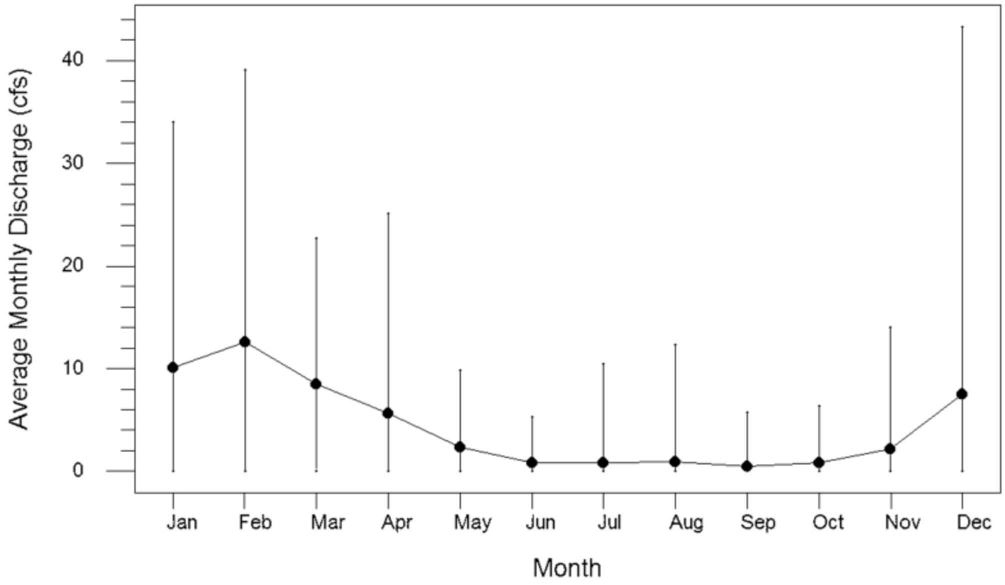
The Pipeline would be adjacent to Kentuck Slough and would cross Willanch Slough upstream from tide gates, in low gradient reaches with associated low gradient floodplains. Echo Creek would be crossed upstream from the confluence with the Coos Bay estuary, a reach that is not tidally influenced. Specific aquatic habitat conditions in those streams (Coos Watershed Association 2006) are consistent with conditions reported for stream reaches surveyed in by ODFW Aquatic Inventories Project and summarized in table 3.5.4-10a.

Stream discharges over the annual cycle are provided in figure 3.5.4-4 for two streams within the Coos Subbasin: Pony Creek—a small, tidally influenced stream and tributary to Coos Bay draining a watershed 3.88 square miles—and West Fork Millacoma River—a large tributary to the Coos River, draining a 46.90-square-mile watershed. Seasonal discharges in West Fork Millacoma River are representative of large and small waterbodies crossed by the Pipeline within the Coos Subbasin. However, flows in Pony Creek have been influenced by releases from Upper Pony Creek Reservoir since construction of the new dam, completed in 2001 (Sol Coast Consulting & Design, LLC and Parsons Brinckerhoff 2009).

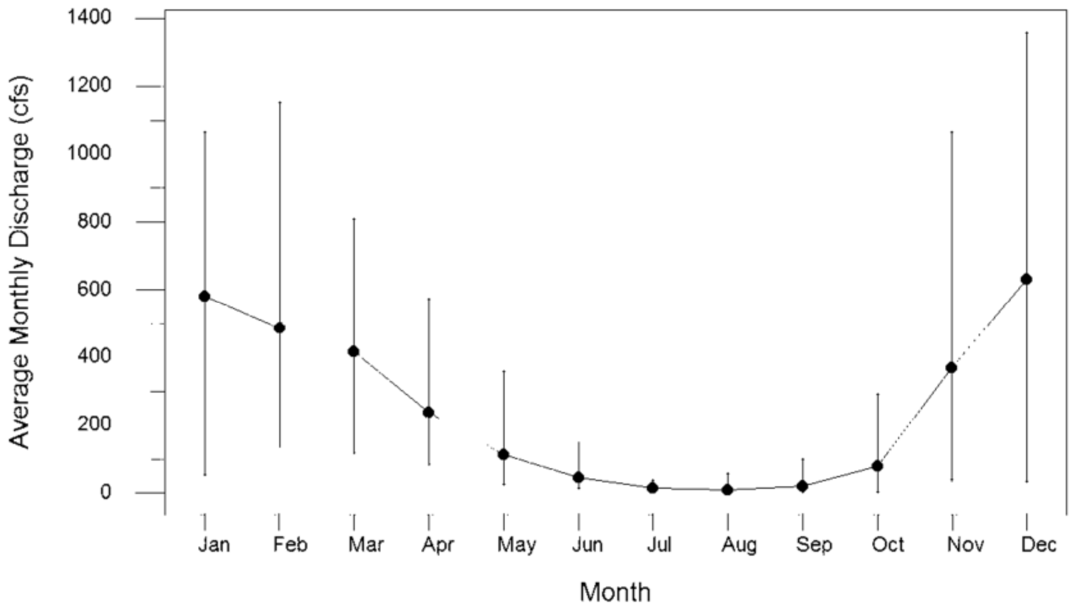
Highest monthly discharges occur between December and April in both waterbodies along with the largest range in variability (maximum and minimum discharge for a given month). Lowest discharges occur between June and October. In all months, minimum discharges in Pony Creek were zero (see figure 3.5.4-4A) and minimum discharges in West Fork Millicoma River were less than 10 cubic feet per second (cfs) during July, August, September and October in some years (see figure 3.5.4-4B). The ODFW (2008) in-stream construction window for coastal tributaries is July 1 to September 15.

Coquille Subbasin - HUC 17100305. ODFW, BLM, and Oregon Forest Industry Council surveyed 336 stream reaches in the four fifth-field watersheds within the Coquille Subbasin that would be crossed by the Pipeline: 18 in the Coquille HUC 1710030505, 76 in the North Fork Coquille River HUC 1710030504, 95 in the East Fork Coquille River HUC 1710030503, and 147 in the Middle Fork Coquille River HUC 1710030501. Surveys were conducted during summers in different watersheds between 1992 and 2005. Conditions for aquatic habitats in the four watersheds are included in table 3.5.4-10a. Sampled reaches of first through fifth order (Strahler numbers 1 through 5) streams had active channel widths averaging less than 3 meters and active channel heights averaging less than 0.6 meter.

Conditions associated with riparian vegetation are generally undesirable in each of the watersheds: there are too few large conifers along most stream reaches and LWD numbers, volume, and presence of key pieces tend to be below benchmark levels, especially for reaches in the Middle Fork Coquille River watershed. Pool conditions tend to more desirable than in the Coos Bay-Frontal Pacific Ocean watershed except for pool complexity formed by LWD, not surprising given the overall undesirable condition for LWD in surveyed streams. Overall, amounts of shade for reaches in the North Fork, East Fork, and Middle Fork Coquille watersheds are at desirable levels (see table 3.5.4-10a), covering more than 80 percent of stream channels.



A



B

Figure 3.5.4-4 Average Monthly Discharge (cfs) in (A) Pony Creek (USGS Gage 14324580) from 1975 to 2008, and (B) West Fork Millicoma River (USGS Gage 14324500) from 1954 to 1981. Vertical lines show maximum and minimum discharges during the periods of record.

Streams in the four watersheds are mostly deeper and narrower (low width/depth ratios) than in the Coos Bay Frontal watershed. Gravel substrates appear to be less limited in reaches within the three watersheds compared to the Coos Bay Frontal. Fine sediments (silt, sand, and organic materials) are present at undesirable levels within many riffle habitat units. These conditions are consistent with summaries of watershed health indicators reported by the Coquille Watershed Association for aquatic/in-stream habitats accessible by Oregon Coast coho salmon (Oregon Watershed Enhancement Board 2007) in lower Coquille River, North Fork Coquille River, East Fork Coquille River, and Middle Fork Coquille River. Conditions for aquatic habitats in the watersheds are included in table 3.5.4-10a. Likewise, BLM (1999a) evaluated habitat conditions in the Upper Middle Fork Coquille Watershed (appendix B.3, table B.3-1b to PCGP's Resource Report 3), noting major problems with erosion and sedimentation due to proliferation of roads during the previous 40 years. Access to upstream habitats was limited by various types of barriers, principally culverts associated with forest roads.

The Coquille Sub-basin was included in NMFS' (2016b) recent evaluation of habitat conditions within Oregon's Mid-south Coast Stratum. Although not specifically addressing the three 5th field watersheds in the sub-basin that would be crossed by the Pipeline, many of the same habitat limiting factors that were described by BLM (1999a) and OregonWatershed Enhancement Board (2007) persist as habitat concerns. The same issues that were discussed above for the Coos Subbasin apply: habitat complexity, fine sediments, stream flows, suitable rearing habitats, refugia, and limited fish passage.

Juvenile salmonid habitat complexity in low gradient streams requires some form(s) of shelter as large wood, pools, connected off-channel alcoves, beaver ponds, lakes, interconnected floodplains and wetlands that provide refugia and shelter from extreme water temperatures and hiding cover from predators (Oregon Watershed Enhancement Board 2007). Spawning gravel quantities, measured by percent of riffle areas covered with gravel and gravel quality depends on embeddedness (percent of riffle areas in silt, sand, and organic fines). Waterbodies in the three watersheds within the Coquille Subbasin that would be crossed by the Pipeline are primarily limited in these and most other aquatic habitat health indicators (see table 3.5.4-11).

Stream discharges over the annual cycle are provided in figure 3.5.4-5 and tributary to Coquille River draining a watershed 73.90 square miles, and Middle Fork Coquille River – a larger tributary to the Coquille River, draining a 305-square-mile watershed.

Highest monthly discharges occur between November and April in both waterbodies along with the largest range in variability (maximum and minimum discharge for a given month). Lowest discharges occur between June and October. Minimum discharges in North Fork Coquille River were less than 10 cfs during August, September, and October in some years (see figure 3.5.4-5A) and were less than 20 cfs during August, September, October, and November in some years in the Middle Fork (see figure 3.5.4-5B). The ODFW (2008) in-stream construction window for the Coquille River and tributaries is July 1 to September 15.

TABLE 3.5.4-11

Comparisons of Aquatic Habitat Watershed Indicators in Fifth-Field Watersheds within the Coquille Sub-Basin that Would Be Crossed by the Pipeline Project from West to East

5th Field Watershed (HUC)	Winter Rearing Habitat Complexity	Summer Rearing Habitat Complexity	Spawning Gravel Quantity	Spawning Gravel Quality	Channel Modification	Large Wood	Water Quality	Water Temperature
North Fork Coquille River (1710030504)	Limiting	Limiting	Moderate	Limiting	Limiting	Limiting	Moderate	Limiting
East Fork Coquille River (1710030503)	Limiting	Limiting	Limiting	Limiting	Limiting	Limiting	Limiting	Limiting
Middle Fork Coquille River (1710030501)	Limiting	Limiting	Moderate	Limiting	Limiting	Limiting	Limiting	Limiting

Source: Oregon Watershed Enhancement Board 2007.

Aquatic habitat categories:

Limiting: indication of degraded watershed health and a significant amount of restoration action is needed to improve watershed conditions.

Moderate: indication of less than desirable watershed health and moderate to significant levels of restoration action is needed to improve watershed conditions.

Adequate: indication of functional watershed health and minimal restoration activities are needed to maintain exiting watershed conditions.

South Umpqua Subbasin – HUC 17100302. The Pipeline would cross five fifth-field watersheds in the South Umpqua subbasin. Between 1992 and 2010, the BLM and Umpqua Basin Fisheries Restoration Initiative surveyed 57 stream reaches in the Olalla-Lookingglass Creek watershed (HUC 1710030212), 97 reaches within the Clark Branch-South Umpqua River watershed (HUC 1710030211), 52 reaches within the Myrtle Creek watershed (HUC 1710030210), 34 reaches within the Days Creek-South Umpqua River watershed (HUC 1710030205), and 28 reaches within the Upper Cow Creek watershed (HUC 1710030206). Conditions for aquatic habitats in the five watersheds are included in table 3.5.4-10b.

Stream reaches sampled in the Olalla-Lookingglass Creek watershed had significantly ($P<0.05$) more area of pool habitats than reaches in the other watersheds of the South Umpqua Subbasin (see table 3.5.4-10b). However, complex pools associated with LWD were undesirably limited (too few pieces per reach length) in most stream reaches for all six watersheds. Conditions for residual pool depths and pool frequencies were mostly intermediate (moderate), neither undesirable nor desirable for most of the sampled reaches in watersheds to be crossed by the Pipeline. Ratios of stream widths to depths in most stream reaches in the six watersheds were generally low, more narrow and deep than wide and shallow. Areas of gravel in riffle habitats were mostly desirable or moderate conditions. Areas of fine sediments in riffles would be undesirable for the majority of stream reaches in the Upper Cow Creek watershed but at moderate or desirable conditions in reaches sampled in the other five watersheds (see table 3.5.4-10b).

Figure 3.5.4-5 Average Monthly Discharge (cfs) in (A) North Fork Coquille Fiver (USGS Gage 14326800) from 1963 to 1981, and (B) Middle Fork Coquille River (USGS Gage 14326500) from 1930 to 1946. Vertical lines show maximum and minimum discharges during the periods of record

Shade conditions would be considered desirable for the majority of stream reaches in all six watersheds but numbers of large conifers in riparian zones were below desirable benchmark levels. LWD conditions in most stream reaches were also below desirable benchmark conditions (see table 3.5.4-10) for all of the watersheds to be crossed by the Pipeline. Likewise, BLM evaluated habitat conditions in the five 5th field watersheds crossed by the Pipeline (see table 3.5.4-1). Summaries of the watershed analyses are provided in appendix B.3 to PCGP's Resource Report 3 (table B.3-1c, table B.3-1d, table B.3-1e, table B.3-1f, and table B.3-1g). As a rule, streams lacked in-stream LWD, fish access was limited, sedimentation was excessive, and habitats had been affected by high flows that degraded in-stream habitats.

The South Umpqua Sub-basin was included in NMFS' (2016b) recent evaluation of habitat conditions within Oregon's Umpqua Stratum. Although not specifically addressing the five 5th field watersheds in the sub-basin that would be crossed by the Pipeline, many of the same habitat limiting factors that were described by BLM nearly 30 years ago persist as habitat concerns. The same issues that were present in the past persist in the South Umpqua Sub-basin: water quantity and quality and stream complexity are the main limiting factors.

Stream discharges over the annual cycle are provided in figure 3.5.4-6 for two waterbodies within the South Umpqua Subbasin, North Myrtle Creek – a small tributary to Myrtle Creek and the South Umpqua River with a 54.2-square-mile watershed, and the mainstem South Umpqua River with a watershed area of 1,670 square miles.

Highest monthly discharges occur between November and April in both waterbodies along with the largest range in variability (maximum and minimum discharge for a given month). Lowest discharges occur between June and October. Minimum discharges in North Myrtle Creek were less than 5 cfs during July, August, September, and October in some years (see figure 3.5.4-6A) and were less than 100 cfs during July, August, and September in some years in the South Umpqua River mainstem (see figure 3.5.4-6B). The ODFW (2008) in-stream construction window for tributaries to the South Umpqua River is July 1 to September 15 and from July 1 to August 31 for the South Umpqua River.

Figure 3.5.4-6 Average Monthly Discharge (cfs) in (A) North Myrtle Creek (USGS Gage 14311000) from 1955 to 1986, and (B) South Umpqua River (USGS Gage 14312000) from 1906 to 2016. Vertical lines show maximum and minimum discharges during the periods of record

The only watershed known to be affected by recent wildfire - the Stouts Creek Fire - is the Days Creek–South Umpqua Watershed. No information comparable to data collected by ODFW Aquatic Inventory and Analysis and reviews prepared by BLM, Forest Service, and/or Oregon Watershed Enhancement Board has been available for the Days Creek–South Umpqua Watershed since the Stouts Creek fire and no documented update of watershed conditions is available.

The Stouts Creek Fire started on June 26 and was contained on July 30, 2015 and burned 12,719 acres in the Days Creek–South Umpqua Watershed (approximately 9.0 percent of the total watershed area), 13,494 acres in the Elk Creek Watershed (approximately 24.8 percent of the total watershed area), and 239 acres in two sub-watersheds within the Upper Cow Creek 5th level Watershed (HUC 1710030206), amounting to 0.5 percent of the total watershed area. The three watersheds are within the South Umpqua Sub-basin (HUC 17100302).

The fire burned 26,452 acres (41.3 square miles), of which 14,251 acres were on National Forest Service land (Umpqua National Forest); 5,544 acres were on BLM Medford District land; and 6,658 acres were on private land. The fire affected from 84 percent to 99 percent of two sub-watersheds in the Elk Creek 5th level watershed (HUC 1710030204): 4,509 acres in Callahan Creek (Lower Elk Creek HUC 171003020404) and 8,024 acres in Drew Creek (Drew Creek HUC 171003020403). The fire also burned 4,008 acres within Hatchet Creek sub-watershed (Corn Creek-South Umpqua HUC 171003020502) and portions of the Stouts Creek sub–watershed (HUC 171003020503) within the Days Creek – South Umpqua 5th level watershed.

The Days Creek–South Umpqua and Elk Creek watersheds were assessed most recently in 2003 by the Umpqua Basin Watershed Council (Geyer 2003c). The 2003 assessment utilizes ODFW habitat benchmarks and measurements to interpret conditions of fish habitat, showing habitat conditions for streams in different 5th field watersheds within the South Umpqua Sub-basin. Specific values for those habitat conditions for streams in the Days Creek–South Umpqua Watershed were provided below in table 3.5.4-10b, and generally coincide with the summary provided in Map 3-3 through Map 3-6 in Geyer (pages 65-68, 2003), especially in categories for conditions of pools and large woody debris (LWD):

> "Of the 84 surveyed stream reaches, only five rate as fair or good in all four categories (6.0%). Sixty-four stream reaches (76.2%) have at least two categories rate as poor. Looking at Map 3-3, it is striking that three-fourths of all reaches rate as poor for large woody material. Over 90% of pools rate as poor or fair (see Map 3-4), and almost half of riffles rate as poor (see Map 3-5). Finally, approximately one third of riparian areas rate as poor (see Map 3-6)."

Key findings for stream functions within the Subbasin focus on stream morphology (most streams have low gradients with few stream miles in source areas where most LWD is recruited; lack of LWD, poor riffle and pool conditions limit fish habitat), stream connectivity (dams and culverts are barriers or impede connectivity and fish access to stream habitats), and channel modifications (many channels have been modified without permits) (Geyer 2003c). Likewise, key findings for riparian zone conditions include riparian tree components (predominant hardwoods and brush/blackberry), riparian vegetation widths or buffers (almost half of potential anadromous salmonid streams have riparian zones that are two trees wide or greater), and riparian shade (potential salmonid streams are predominantly shaded by vegetation or infrastructure, but over a third are less than half covered). Further, water temperatures in reaches of multiple streams in the Sub-basin were found to be limited by ODEQ (in years 1998 and 2002) water quality standards based on salmonid tolerance levels. Alternatively, no streams in the sub-basin were on the ODEQ 303(d) list for sedimentation (total suspended solids, TSS) or for turbidity (as nephelometric turbidity units, NTU) at the time the watershed assessment was prepared (Geyer 2003c).

Data provided by the Umpqua National Forest (Forest Service 2015) on modeled effects of the Stouts Creek fire (eg. Cannon et al. 2010) and reviews of scientific studies related to post-fire stream discharge, surface erosion, and effects to water quality (Hallema et al. 2017) and salvage logging effects on sediment transport (Silens et al. 2009) were combined with the most recent Oregon Watershed Enhancement Board 2003 watershed assessment for the South Umpqua Subbasin (Geyer, 2003c), which includes the Days Creek-South Umpqua Watershed. That investigation estimated that debris-flow volumes would increase with basin size and distance along the drainage network, but some smaller drainages were also predicted to produce substantial volumes of material. The predicted probabilities and some of the volumes predicted for the modeled storms indicate a potential for substantial debris-flow delivery to coho salmon-bearing streams and designated critical habitats downstream in Stouts Creek, lower East Fork Stouts Creek, Hatchet Creek, Callahan Creek, and Drew Creek. All are tributaries to the South Umpqua River for which water quality is likely to decline due to increased delivery of sediment because of the Stouts Creek Fire.

According to geographic data developed by the Umpqua National Forest and GIS shapefiles provided to Edge Environmental, Inc., 9.14 mi^2 in the Stouts Creek Fire perimeter were unburned or burned with very low intensity (22.1 percent), 11.55 mi^2 (28.0 percent) burned with low intensity, 13.70 mi^2 (33.2 percent) were moderate, and 6.90 mi^2 (16.7 percent) burned with high intensity. Areas of high severity burn were extensive in headwaters of Hatchet and Callahan creeks and smaller drainage areas in Drew Creek. Those drainages support Oregon Coast coho and designated critical habitat (0.7 mile in Hatchet Creek, 3.6 miles in Callahan Creek, and 2.6 miles in Drew Creek). According to the Umpqua National Forest (Forest Service 2015), post-fire runoff, erosion, and debris flows risks would increase in Hatchet and Callahan creeks along with increasing risks of spawning and rearing habitat degradation. Roads are also likely to be impacted from higher runoff and debris flows, scouring roadbeds and increasing sedimentation to coho habitat (Forest Service 2015).

Forest fires can lead to increased peak instream discharge and surface erosion; effects to water quality and aquatic habitats are exacerbated by increased wildfire severity over larger areas of slopes that lead to increased overland flow of eroded materials (Hallema et al. 2017). In addition, soil texture, litter cover, soil moisture and organic matter are affected by wildfire duration and fire temperature which can lead to soil water repellency and decreased water infiltration (Hallema et al. 2017). Further, research has shown that post-fire salvage logging increases mass wasting by creating more effective terrestrial sediment transport networks to stream channels, thus delivering more sediment than burned watersheds without salvage logging (Silins et al. 2009). Wildfire has also been found to increase concentrations of phosphorous in burned and post-fire, log-salvaged streams which elevated algal production and increased stream primary productivity, levels of secondary invertebrate consumers, and increased size and growth rates of fish as tertiary consumers (Silins et al. 2014).

USGS has developed empirical models to estimate probabilities for the occurrence and volume of post wildfire debris flows (Cannon et al. 2010). The models describe debris-flow probability as a function of readily obtained measures of areal burned extent, soil properties, basin morphology, and rainfall from short-duration and low recurrence-interval rainstorms and describe debris-flow volume as a function of drainage basin gradient, extent of area burned, and storm rainfall. The models have been applied to burned watersheds in the Intermountain West and the Pacific Coast by USGS Landslide Hazards Program and include modeling predicted debris flows after the Stouts Creek Fire. USGS conducted a post-fire debris-flow hazard assessment for the Stouts Creek Fire using geospatial data related to basin morphometry, burn severity, soil properties, and rainfall characteristics to estimate the probability and volume of debris flows that may occur in response to a design storm (the model results are available online at https://landslides.usgs.gov/hazards/postfire_debrisflow/).

For model applications, the Stouts Creek Fire area was divided into 324 discrete drainage mini-basins with areas averaging 0.57 km^2 (ranging from 0.02 km^2 to 7.43 km^2). Estimated debris-flow probabilities in the drainage mini-basins ranged from 0 to >80 percent in response to the rainfall intensity for a 2-year recurrence interval rainstorm measured for 1-hour duration along with rainstorm interval recurrences of 5-years, 10-years, 25-years, 50-years and 100-years.

Basins and drainage networks with the highest volumes of debris flows following 2-year, 5-year, and 10-year recurrence interval rainstorms tended to be in the center of the fire area, centered on Hatchet Creek in the Corn Creek sub-watershed (HUC 171003020502), in the eastern portion of the Stouts Creek sub-watershed (HUC 171003020503), and the headwaters of Callahan Creek (Lower Elk Creek sub-watershed, HUC 171003020404) and Drew Creek (Drew Creek sub-watershed, HUC 171003020403). Highest volumes for predicted debris flows averaged 180,303 m^3 (ranging from 82,574 m^3 up to 445,238 m^3 in 12 mini-watersheds where probabilities were 0 to 20 percent for 9 of the 12 watersheds following a 2-year recurrence interval rainstorm). Probabilities and predicted debris flow volumes following different rainfall recurrence intervals are provided in appendix M, table M-8.

Estimated debris-flow volumes increase with basin size and distance along the drainage network, but some smaller drainages were also predicted to produce substantial volumes of material. The predicted probabilities and some of the volumes predicted for the modeled storms indicate a potential for substantial debris-flow delivery to coho salmon-bearing streams and designated critical habitats downstream in Stouts Creek, lower East Fork Stouts Creek, Hatchet Creek, Callahan Creek, and Drew Creek. All are tributaries to the South Umpqua River for which water quality is likely to decline due to increased delivery of sediment because of the Stouts Creek Fire. Consequently, post-fire effects to water quality and streambed substrates in this portion of the South Umpqua Subbasin are expected.

Critical Habitat

Using available spatial data from ODFW on specific occupied stream reaches (ODFW 2014c), NMFS developed critical habit information based on fifth-field watersheds to designate specific streams as critical habitat within watersheds, including the 10 watersheds that would be crossed by the Pipeline. Included in the designation of critical habitat for the Oregon Coast coho are estuaries associated with the watersheds, beginning at the estuary mouth, including the entrance to the Coos Bay estuary at the land end of North Jetty and South Jetty. Critical habitats for Oregon Coast coho in specific waterbodies crossed by the Pipeline are compiled in appendix M and are summarized in table 3.5.4-12. Critical habitat includes the Coos Bay estuary and 25 freshwater streams in which critical habitat for Oregon Coast coho salmon has been designated (NMFS 2008d). Critical habitat is designated within 6,568 stream miles in 81 fifth field watersheds covering a total of 10,751 square miles with 7,342 stream miles of current and/or historically occupied habitat. Approximately 27 percent of critical habitat for the Oregon Coast coho ESU is within the three subbasins in table 3.5.4-12: 2.9 percent is in the Coos Bay Frontal-Pacific Ocean; 4.0 percent is within the three fifth field watersheds crossed in the Coquille Subbasin; and 4.9 percent is within the five fifth field watersheds crossed in the South Umpqua Subbasin.

3.5.4.3 Effects of the Proposed Action

Analyses of effects for coho salmon in the Oregon Coast ESU are addressed separately for the marine analysis area, estuarine analysis area, and riverine analysis area.

Direct and Indirect Effects – Marine Analysis Area

Potential project-related effects to Oregon Coast coho within the marine analysis area include 1) acoustic effects to coho from LNG carriers transiting the marine analysis area, and 2) the inadvertent release of oil, gas and fuel from LNG carriers at sea.

<u>Acoustic Effects</u>

Underwater noise may affect coho salmon in the Oregon Coast ESU. LNG carriers transiting the marine analysis area would produce underwater noise. Underwater noise levels are expected to vary by ship type and also by carrier length, gross tonnage, carrier speed, and, to some extent, carrier age—older carriers tended to be louder than newer carriers. Based on the general trend for higher underwater noise generated by larger carriers (McKenna et al. 2012), it is possible for some of the LNG carriers that would utilize the LNG Terminal to generate more noise than the

LNG tanker built in 2003 with 138,028 m^3 capacity reported by Hatch et al. (2008) that produced sound levels (with 1 standard error) of 182 ± 2 dB re: 1 μPa @ 1 meter.

State agencies in Washington, Oregon, and California, along with federal agencies have developed interim noise exposure threshold criteria for pile driving effects on fish (WSDOT 2011a; Fisheries Hydroacoustic Working Group 2008, Popper et al. 2006). These threshold criteria are considered levels below which injury effects would not occur to fish, including salmonids, from in-water noise. As a result, these thresholds should be suitable for all forms of in-water noise. Interim noise exposure threshold criteria for pile driving effects on fish (WSDOT 2011a) include 1) a SEL_{cum} of 187 dB re 1 μPa^2 s for fishes more than two grams, 2) a SEL_{cum} of 183 dB re 1 μPa^2 s for fishes less than two grams, and 3) an SPL_{peak} of 206 dB re 1 μPa for all sizes of fishes (WSDOT 2011a).

The LNG tanker in the Hatch et al. (2008) study produced sound levels (with 1 standard error) of 182 ± 2 dB re: 1 μPa @ 1 meter that attenuated to 160 dB at 35 ± 11 meters and to 120 dB at 16,185 ± 5,359 meters. All values are less than those noted above as causing direct harm to fish, with the possible exception of very small fish within one meter (three feet) of the hull for an extended period. Additionally, since carriers are in transit and fish can easily move away from carriers, fish exposure would be very brief, further reducing the chance for noise exposure that would result in adverse effects.

It is likely that any LNG carrier noise generated in the marine analysis area would be below thresholds for adverse effects to fish with the possible exception of those fish very near the hull for extended periods, which would be an unlikely event. Noise from LNG carriers would likely increase the background noise within the marine analysis area, which is occurring globally (Slabbekoorn et al. 2010). While background levels are not specifically known in the marine analysis area, analyses of more recent vessel-traffic related noise shows that such levels along the US west coast are holding steady or increasing slightly offshore from Southern California but decreasing in the area off Oregon and Washington (Andrew et al. 2011). Oregon Coast coho in the marine analysis area might detect noise from LNG carriers but are not expected to be adversely affected. Ship noises from LNG carriers transiting the marine analysis area are not expected to adversely affect Oregon Coast coho salmon.

Fuel or Oil Spills at Sea

The LNG carriers use either a steam or duel fuel diesel electric propulsion system that is primarily fueled by natural boil-off gas. Fuel (e.g., diesel) used for back-up generation for LNG carrier propulsion and oil or hydraulic fluids used for mechanical equipment could possibly leak or be inadvertently spilled while the carriers are in transit. The low volume of petroleum oils and fuel on LNG carriers greatly reduces chance of impacts in the marine environment from petroleum spills. The Federal Water Pollution Control Act, as amended by the CWA (33 U.S.C. 1251–1387), prohibits the discharge of oil upon the navigable waters of the U.S. LNG carriers calling on the LNG Terminal would also be required by the Coast Guard to have a vessel response plan in order to be adequately prepared for accidental spills. Therefore, neither fuel nor oil leaks from LNG vessels transiting in the waterway to and from the LNG Terminal are likely to have adverse effects on aquatic resources including coho salmon.

Direct and Indirect Effects – Estuarine Analysis Area

Potential project-related effects to coho salmon in the Oregon Coast ESU within the estuarine analysis area include 1) turbidity effects from dredging the slip and access channel, 2) turbidity effects from LNG carrier propeller wash and ship wake, 3) suspended sediment released during HDD construction across Coos Bay Estuary and Coos River, 4) stranding Oregon Coast coho by LNG carrier ship wake, 5) introduction of exotic, invasive species from ballast water, 6) entrainment and impingement of Oregon Coast coho in LNG carriers' intake port, 7) estuary water cooling during LNG carrier cargo loading, 8) effects from operational lighting, 9) acoustic effects to coho during LNG Terminal construction, 10) habitat modifications related to the slip, access channel, NRI areas, and pile dike rock apron, 11) restoration activities at the Kentuck Mitigation Site, 12) shading, 13) nuisance species introduction, and 14) food organism entrainment.

Timing to Life History Functions

In-water construction of the JCEP Project within the Coos Bay estuary is planned from October 1 through February 15 following ODFW's recommendation (ODFW 2008). This work window applies to Coos Bay estuary and estuarine portion of the Coos River (upstream to Millicoma-South Coos River confluence), which coincides with adult upstream migrations of coho (see figure 3.5.4-1, above).

Approximately one-half of each brood of coastal coho salmon in Winchester Creek/South Slough (tributaries to Coos Bay) moved to the estuary as sub-yearlings (Miller and Sadro 2003). The estuary provides feeding and migratory habitat for adult and maturation habitat for juvenile coho that inhabit the ecotones between freshwater and saline portions of the estuary for up to 8 months and then move back upstream to overwinter. By October, adult coho salmon would likely have migrated from critical habitat in the estuary to upstream spawning habitats but the timing and progress of upstream migration could be influenced by drought and autumn precipitation. For example in fall 2011, significant rainfall did not occur until late December and adult coho held in mainstem pools for an extended period, waiting for rainfall, followed by increased discharge (ODFW 2012a). Adult coho could be present in designated critical habitat within the estuary, coincidental with in-water construction for the Project. Principal direct impact during in-water construction would most likely be related to acoustic effects and turbidity generated by dredging and construction of the slip and access channel andthe Navigation Reliability Improvements. In the unlikely event of an inadvertent release of drilling mud into the estuary during HDD construction, this may also cause a direct affect

Turbidity Effects from Dredging in Coos Bay

Construction of the LNG Terminal slip would require the excavation and dredging of the shoreline of Coos Bay near Jordan Cove, including removal of about 5.7 mcy of sediment as part of the development of a slip and access channel. The 5.7 mcy of materials would be used to raise the elevation of the LNG Terminal and the South Dunes site to elevations above the tsunami inundation zone.

At least 3.6 mcy would be removed behind a berm in upland habitat away from the bay, with little potential for sediments to affect the marine environment. The remaining 2.1 mcy would be removed by dredging of the berm (0.7 mcy) and the new access channel (1.4 mcy) in the bay (see discussion in section 3.5.1.3, green sturgeon).

Turbidity was modeled for new construction was based on the anticipated geotechnical and environmental conditions for this project using the COE's DREDGE model and two dimensional numerical model Mike21 (see discussion in section 3.5.1.3, green sturgeon). Increases in suspended sediment and turbidity levels in the bay due to construction-related dredging would persist for a short period of time (4-6 months) affecting a relatively limited area. Modelling at the access channel has demonstrated the maximum turbidity plume extent, defined by the simulated 10 NTU above background contour, to be approximately 780 and 750 feet when using cutter suction and clamshell dredges respectively. (Moffatt & Nichol 2017c). Therefore, short-term increases in turbidity above background levels would occur in the vicinity of dredging activity. Due to the limited extent of increased suspended sediment during periods when rearing coho salmon are not abundant and the likely ability of juvenile and adult fish to avoid active construction areas, substantial adverse effects to coho salmon would not occur from slip and access channel construction.

During capital dredging, a total of approximately 590,000 cy of dredge material will be removed from four locations (referred to as Dredge Areas 1 through 4) adjacent to the existing Federal Navigation Channel between RM 2 and 7. These areas will be dredged to a controlled depth to match the adjacent Federal Navigation Channel, which is currently -37 feet MLLW.

Dredging methods will be similar to what is described above for the slip and access channel, and could include mechanical methods from a barge or hydraulic cutter section dredging. Material from the four dredge areas will be moved to the APCO Sites. The potential turbidity plume extents, defined by the simulated 10 NTU above background contour, from the Navigation Reliability Improvements varies by location and dredge equipment but could extend from 2,820 feet to 4,600 feet from the activity depending on the ebb and flow of the tidal current and extent of additional sediment generated. However, this increased turbidity would be expected to be short-term (Moffatt & Nichol 2017c). See the green sturgeon section for more information on dredging in the NRI.

The ambient suspended sediment levels in the water (generated by flows, waves and ship traffic) create a background level of suspended sediment. Within Coos Bay, suspended sediment measurements taken at the Charleston Bridge over a 2-year period show an average summer turbidity level of 10 mg/l and an average winter level of 27.3 mg/l.[8] Some individual events (e.g., winter storms) measured at the Charleston Bridge were recorded between 100 and 500 mg/l. Aquatic organisms in Coos Bay are adapted to and exposed to periods of high to moderate turbidity during the winter months. Dredge operations are expected to result in similar effects, with higher concentrations of suspended sediments in the immediate area of dredging.

At the Eelgrass Mitigation site, a total of 40,000 cy of dredge material will be removed most likely with a small hydraulic dredge. Modeled turbidity values were determined to range from 270 to 290 NTUs. The potential turbidity plume extents, defined by the simulated 10 NTU above background contour, from the excavator dredge area would be generally limited to between 340 and 360 feet in all directions (Moffatt & Nichol 2017c). Since the site is a more confined and shallow area with somewhat limited circulation, the turbidity plume would be

[8] Jordan Cove included in its application to the FERC a study by Moffatt & Nichol entitled "Report on Turbidity Due to Dredging," attached as appendix F.2 of Environmental Resource Report 2 submitted May 2013.

maintained within the local area of excavation. The duration of suspended sediment settling, therefore, is expected to be very short with turbidity dissipating to background levels within an hour after dredge operations cease, depending on the tidal cycle. Turbidity controls utilized during construction are anticipated to minimize risk of turbidity associated with the eelgrass mitigation area. See the green sturgeon section for a discussion of these controls.

If coho salmon are exposed to moderate to high levels of suspended sediment for prolonged periods, a number of adverse effects could occur including behavioral changes, sub-lethal effects, and increased mortality from predators. The exposure of listed fish to increased suspended sediment may result in a behavioral response to move to locations with lower concentrations of sediment. If fish failed to avoid increased suspended sediment, such exposure could result in gill irritation or abrasion, which can reduce respiratory efficiency or lead to infection and a reduction in feeding efficiency due to reduced visibility. However, suspended sediment concentrations resulting from in-water construction are unlikely to reach levels that would cause these results except in the immediate vicinity of dredge operations. Dredging is expected to create localized, short-term spikes of high to moderate TSS and turbidity. Effects to salmonids are expected to be slight due to the limited area affected in the bay and limitations on construction periods. Rearing and migrating coho, which should be uncommon in Coos Bay during the in-water work window, would likely avoid active work areas.

Although localized, short-term, elevated levels of TSS concentrations and turbidity are anticipated from access channel and slip formation, and the NRIs such conditions may result in behavioral changes that could affect Oregon Coast coho salmon.

Contamination Effects from Dredging

NMFS (2009c) has noted that subadults and adults feeding in bays and estuaries may be exposed to contaminants that may affect growth and reproduction. Such effects due to bioaccumulation of pesticides and other contaminants have been documented in white sturgeons that also inhabit West Coast estuaries (NMFS 2009c). Sediments within the proposed dredge prism for the access channel were sampled to determine whether they meet Dredged Material Evaluation Framework (DMEF) guidelines, as identified for the Lower Columbia River Management Area, for in-water disposal (SHN 2006). An analysis of grain size distribution and total volatile solids composition was initially performed to determine if the sediments require further testing for chemical analysis. All of the samples were primarily composed of medium to fine grained sand and had a very low percentage of total volatile solids. Since none of the samples exceeded 20 percent fines or 5 percent total volatile solids, no further chemical testing was required and the sediments were deemed suitable for in-water disposal, according to DMEF guidelines. These findings indicate that resuspension of sediments associated with the dredging for the access channel should not result in significant increases the bioavailability of contaminants to fish and fish food organisms within the Project analysis areas.

This conclusion is further supported by previous sediment evaluations conducted for Coos Bay channel maintenance and improvement dredging. Most recently in 2004, the COE performed sediment sampling and characterization at various stations along the Federal Navigation Channel (COE 2005). Throughout the entire sampling area, only low levels of sediment contaminants were identified, with all levels well below their respective DMEF screening levels. One of the sampling stations (0915CB-BC-10) was located approximately 0.4 mile downstream of the LNG

Terminal. The 2004 sediment sampling effort found only low levels of chemical contaminants, with all levels below their respective DMEF screening levels. None of the samples contained DDT or its derivative by-products (DDE, DDD, see section 3.5.1.3, green sturgeon) at levels that could cause adverse effects to fish resources.

In 2011 and 2016, JCEP conducted geotechnical investigations at the NRI sites to support the JCEP's DMMP. Analysis of the physical characteristics of sediments at the NRI sites determined that sediment composition consisted of sand, silty sand, sandstone, and siltstone. This is similar to the character of sediments collected from the adjacent FNC and from within the footprint of the proposed LNG Terminal access channel. These sediments were generally described as coarse-grained with high sand content, which the Portland Sediment Evaluation Team (PSET) previously determined suitable for unconfined aquatic disposal. Due to their proximity to previous sampling locations in the FNC and access channel, sediments to be dredged from the NRI areas are expected to have a chemical character similar to the FNC and access channel sites with low likelihood of potential contaminants. Therefore, it is expected they also would be suitable for unconfined aquatic disposal.

Turbidity Effects from Temporary In-water Construction

In-water construction activities are likely to temporarily increase TSS concentrations and turbidity. Such increases would result from in-water construction related to the:

- Temporary Material Barge Berth (TMBB),
- Material Offloading Facility (MOF),
- Pile Dike Rock Apron,
- Trans Pacific Parkway/US-101 Intersection Widening,
- APCO Site access bridge construction,
- replacement of anchoring systems for existing meteorological ocean data collection buoys as well as addition of anchoring systems for two new buoys,
- establishment of hydraulic connections to the Kentuck Project for estuarine habitat mitigation, and
- creation of the Eelgrass Mitigation site.

Turbidity increases would be localized and limited to the time required to complete each of the respective JCEP Project components. Minor, localized increases in suspended sediments (resuspension lasting a few hours to a few days) may continue to occur until all disturbed materials in the construction area have been flushed out. Implementation of erosion and sediment control measures and in-water work conservation measures will greatly reduce the duration and intensity of sediment and turbidity in the waterways (see appendix N). The exposure of listed fish to increased suspended sediment may result in a behavioral response to move to locations with lower concentrations of sediment. If fish failed to avoid increased suspended sediment, such exposure could result in gill irritation or abrasion, which can reduce respiratory efficiency or lead to infection and a reduction in feeding efficiency due to reduced visibility. However, suspended sediment concentrations resulting from in-water construction are unlikely to reach the levels that would cause these results. Increased turbidity may affect OC coho that occur in the immediate vicinity of construction.

Turbidity Effects – LNG Carriers in the Waterway

Propeller wash from LNG carriers and tug boat propellers associated with the Project, as well as ship wakes breaking on shore, could cause increased erosion along the shoreline and re-suspend the eroded material within the water column and displacing bottom organisms due to bottom scour. This may affect the diversity and health of the benthic community regarding food availability and feeding conditions for foraging and migrating fish species (see discussion in section 3.5.1.3, green sturgeon). Waves from vessels breaking on the shoreline can also cause fish stranding (see discussion below). The possible magnitude and effects of the proposed Project including approximately 120 LNG carrier round trips per year on shoreline erosion were approximated by JCEP through model studies, the results of which are discussed below. The possible magnitude and effects of the proposed Project on shoreline erosion were approximated by JCEP through model studies, the results of which are discussed in detail in section 3.5.1.3 and are summarized below. Overall effects on bank and bottom erosion and elevated suspended sediment effects are expected to be unsubstantial.

Models were developed to assess the likely size of waves hitting the shore relative to existing conditions. Additional models assessed likely magnitude of propwash effects on the channel and docking area (see section 3.5.1.3, green sturgeon). The results of the wave model indicated that waves resulting from 120 round trips per year were not greatly different in most areas than natural conditions. The Moffatt & Nichol (2008a) model found that the maximum wave height generated would be about 1.1 feet. Although waves of this size occur throughout much of the bay, they only occur about 2 percent or less of the time annually based on the locations modeled. Among the seven locations chosen by Moffatt & Nichol, the model predicted that the waves generated would equal from 0.0 to 3.1 percent of the annual wave energy at these locations above the current wave energy level. A separate wave model estimate estimated that additional waves generated by the new LNG traffic could increase shoreline sediment transport at the modeled point by 5 to 8 percent over existing conditions (wind-generated waves plus existing large vessel–generated waves). The effect on turbidity relative current conditions would likely be slight and not directly affect coho salmon.

The models addressing propwash effects had similar likely low effects on turbidity. The model by Moffatt & Nichol (2008a) generally found along most of the route no marked bottom disturbance or sediment suspension would occur, as the increased velocity would be similar to maximum tidal currents. Within about the last half- to quarter-mile before reaching the slip (based on the point selected for modeling) is where bottom velocity is increased. Some increased bottom scour and locally elevated turbidity may occur in this area but the effects would be limited in dimension. Disturbance would be limited, partly due to the coarse (mostly sand) bottom substrate that is relatively resistant to resuspension and rapidly settles. A separate model by CHE (2011) found bottom velocity greater than about 4 ft/sec would occur only in an approximate 80-foot-wide band. Therefore, velocity generated by the propeller in excess of tidal flow velocity would be limited to a narrow band in the mid-channel, limiting the area where sediment may be suspended from propeller actions of the LNG vessel. However, this region is generally of coarser sediment that is less prone to suspension. Turbidity would likely be slight due to the coarse characteristics of the navigation channel sediment that is resistant to current-induced suspension. Some increased velocity would occur in the docking area. Sediment analysis suggests that over 95 percent of the bottom material (mostly silt/clay size) in the access channel would be susceptible to suspension at this velocity. The report also estimated that bottom scour would be limited to about two inches over a limited bottom area (approximately 100 by 50 feet) in the access channel. Some bottom disturbance would likely occur during docking but over a very small area.

A more recent vessel wake analysis was recently completed (Moffatt & Nichol 2017d). This study compared two modeling scenarios – “without project” and “with project.” The “with project” scenario included the latest anticipated dredged depths for the federal navigation channel, access channel, and marine slip. This study also incorporated the latest anticipated vessel characteristics for the new facility, which included 240 vessel transits, bulk carriers and tugs. For the “with project” scenario, all LNG carriers were assumed to travel no faster than 5 knots, with tugs traveling up to 10 knots outbound. Results of the 2017 wake analysis are summarized below.

The results of the more recent vessel wake analysis indicates the drawdown generated by LNG carriers’ departure and arrival under the proposed project would be lower than existing conditions (0.4 - 0.5 feet for bulk carriers compared to 0.1-0.2 feet for LNG carriers at the shoreline). The predicted wave heights at the shoreline are higher with the tugs (0.6 – 0.8 feet) than with the bulk carriers under the proposed Project. However, even the magnitude of tug wakes would be at the low end of the locally generated wind-wave heights ranging from about 0.5 to 3 feet (CHE 2011, Moffatt &Nichol 2017e). . The wave effect on the shoreline from increased vessel transits with the JCEP can be managed by reducing vessel speed (Moffatt & Nichol 2017e).

An updated 2017 prop wash memo (Moffatt & Nichol 2017e) included modeling the use of ship engines and tug assist for berthing and unberthing in the marine slip area. Results indicated high propeller wash velocities along the east side of the slip during unberthing. The largest bottom velocities (13.6 feet/sec) were estimated to occur on the eastern side of the Access Channel and the Slip near the MOF. During berthing, the largest bottom velocities (5.4 feet/sec) are expected to be near the western slope within the Slip and the Access Channel.

Scour depths were estimated to be nearly 0.5 feet due to propeller wash in the Access Channel and the Slip near the eastern side of the Access Channel and the Slip if there is no slope protection installed. However, slope protection is planned for each side of the slip, and for the east and west sides of the access channel. These results do not change the earlier conclusion that suspended sediment levels during carrier docking are expected to only have short-term localized effects to Oregon Coast coho that may occur in the docking area.

Overall, models indicated some additional shore sediment movement could occur from the waves generated by the passage of LNG vessels through Coos Bay, particularly the tug vessels, the effects would be small because increased waves would occur infrequently, contribute a very small portion of total annual wave energy and sediment transport, and be within the normal magnitude of waves that naturally occur within the bay. Additionally bottom disturbance would likely occur during LNG vessel transit in the main channel where sediment is coarse and also during docking. In most cases, this disturbance is likely to be much less than estimated because of the conservative assumptions used for this model. Therefore, the total effect of suspended sediment is likely to be within the range of natural annual variability of wave conditions. Elevated suspended sediment levels from transit and docking are consequently expected to be brief and localized, having only short-term local effects to any Oregon Coast coho salmon along the route or in the access channel and marine slip area.

Erosion and Runoff from Coos Bay Upland Facilities

Impacts on marine resources could occur from the clearing of vegetation at the terminal, erosion and sediment runoff, and potential hazardous substance spills during construction. While no streams are present in the upland portion of the terminal, the removal of current vegetation could modify the character and amount of water runoff into the bay.

Nearshore vegetation clearing could indirectly affect aquatic resources in the bay. However, the amount of nearshore vegetation that would be removed for this Project is small. Other than an existing disturbed shoreline near the South Dunes site that would be used as a temporary laydown area, no planned nearshore disturbance would occur outside of the upland and shoreline excavated and dredged to create the marine slip for the terminal.

During construction, uncontrolled increases in sediment runoff to Coos Bay could impact local aquatic resources. JCEP would prevent uncontrolled releases of sediment runoff during construction by implementing erosion control and revegetation measures from its Plan and Procedures. Additionally, accidental spills of hazardous materials (e.g., equipment fuel, oils, and paints) during construction could have effects on aquatic resources in the bay. JCEP prepared a draft site-specific SPCCP to minimize the potential for accidental releases of hazardous materials.

Stormwater Discharge

LNG Terminal

Stormwater discharge has the potential to contain chemicals toxic to coho salmon. However the NPDES permit that the applicant would be obtained requires discharges to not modify state water quality standards of the receiving water (see discussion in section 3.5.1.3, green sturgeon). The proposed oil and grease treatment system is designed to limit discharges of oil and grease. This system design would ultimately need approval from the State to obtain the NPDES permit (see discussion in section 3.5.1.3, green sturgeon).

Trans Pacific Parkway/US-101 Intersection Widening

Stormwater generated as a result of new impervious area at the Trans Pacific Parkway/US-101 Intersection Widening will be collected and conveyed to treatment facilities to provide treatment for 100% of the 2-year storm event. Drainage curbs will be installed near the edge of pavement along the northwest side of the roadway. These drainage curbs will collect and convey flow from the road crown to water quality treatment facilities. The water quality facilities will provide treatment for the design flow volume and bypass higher flows before discharging the runoff into Coos Bay.

APCO Sites

APCO Site 1 (East) will be surfaced with dense-graded gravel and will have existing drainage patterns will be preserved to the maximum extent practical. Stormwater will be treated primarily by vegetated swales and filter strips. Fill placed on APCO Site 2 (West) will be surfaced with native vegetation. Additional storm water controls will be added if necessary. The bridge connecting APCO Site 1 and 2 is in preliminary design. The stormwater run-off from the bridge will be treated prior to discharge to Coos Bay.

PCGP Contractor Yards

PCGP has proposed contractor yards that border Coos Bay at the shore and another that borders Isthmus Slough at the shoreline, all designated critical habitat for coho. Several other proposed yards border or are close (<100 feet) to waterbodies inhabited by Oregon Coast coho. Although the yards are previously disturbed industrial sites, stored materials and surface runoff could enter Oregon Coast critical habitat. Any potential risks due to surface runoff will be mitigated through implementation of an approved stormwater management plan.

Kentuck Project Site

Roadway improvements associated with the Kentuck Project, which include elevating and re-paving of East Bay Drive and Golf Course Lane, will result in the addition of new impervious area. The stormwater facilities at the Kentuck Project site will be designed to provide treatment for 100% of the 2-year storm event wherever feasible.

East Bay Drive will sheet flow stormwater runoff to roadside drainage curbs. Once along the curb, water will flow toward cartridge filters, which will treat water before discharging the runoff onto rip-rap road base adjacent to the receiving waters in Kentuck Inlet.

Along most of Golf Course Lane, surface water ditches and flow-through bio-infiltration conveyance systems are proposed. In these areas, collected flow that does not fully infiltrate into the underlying well-draining soils will be conveyed to an outfall into the Kentuck Slough. At the north end of Golf Course Road, runoff will be collected in drainage curbs and conveyed to cartridge filters before discharging to Kentuck Slough.

Temporary Construction Facilities

Construction laydown areas will be surfaced to a large extent with larger, open-graded aggregate that will allow infiltration; therefore, stormwater from these areas will be self-contained and will infiltrate without the need for outfalls. Impervious surface will not be added at the Pony Village and Myrtlewood Offsite Park & Rides for the JCEP Project Area. Stormwater treatment for temporary facilities is described further in JCEP's Resource Report 2 (Storm Water Management Plan appendix), and the ESCP in an appendix to JCEP's Resource Report 7.

<u>Stranding from Ship Wake</u>

Fish stranding can occur when fish become caught in a vessel's wake and are deposited on shore by the wave generated by the vessel wake. Stranding typically results in mortality unless another wave carries the fish back into the water. Pearson et al. (2006) in a study of fish stranding noted that a series of interlinked factors act together to produce stranding during vessel traffic and may include water surface elevations, with low tides more likely to result in strandings than high tide; beach slope, with strandings more likely on low gradients than high; wake characteristics influenced by vessel size, hull form, depth underwater (draught), and speed with faster speed producing larger wakes; and biological factors, such as numbers of small fish present near the shoreline and whether or not fish are strong swimmers (see discussion in section 3.5.1.3, green sturgeon). All of these factors can vary simultaneously, making it difficult to predict the location and to what degree strandings may occur. A few areas may have the potential to strand fish in Coos Bay. One is the mud flats on the west side of the navigation channel along the Coos Bay and Empire Range that have beach morphology that has been shown to have potential for stranding, especially at low tide. The sizes of juvenile coho in the estuary are expected to be comparable to sizes of juvenile Chinook salmon (less than 9 cm) that became stranded by ship wakes in the Columbia River (Pearson et al. 2006); juvenile coho may be susceptible to stranding by ship wake.

Ship wakes produced by deep-draft vessels traveling at speeds greater than the estimates for LNG vessel speeds along most of the route within the Coos Bay estuary have been observed to cause occasional stranding of juvenile salmon with no observed strandings as a result of vessels traveling at speeds under 9 knots (10.4 mph) (Pearson et al. 2006). The hull geometry of the LNG vessels is such that bow wakes are minimized, especially at the slower speeds of 4 to 6 knots (4.6 to 6.9 mph) that would occur during most of the transit route through Coos Bay. The one exception is near the Coos Bay entrance (first mile), when vessels may be traveling 8 to 10 knots (9.2 to 11.5 mph). While waves generated in this region may be larger than farther in the bay, this is an area likely already receiving larger ocean-generated waves, so the vessel-generated waves would be little different than current conditions in this region.

Therefore, the LNG carriers would be traveling along most of the route at speeds less than that observed (Pearson et al. 2006) to cause stranding. In models and research conducted by JCEP, wave heights produced by LNG vessel traffic would not exceed that of normal conditions in Coos Bay and overall waves would contribute to a small portion of the total waves that occur in the bay. In addition, the LNG carriers would be arriving and leaving at high tide, which is a period when gently sloping beaches are mostly covered and less likely dewatered from waves. Considering that LNG marine traffic (about 120 inbound and 120 outbound trips per year) would enter and leave at high slack tide, have mostly low vessel speeds, and wave height would be in normal range, it appears unlikely that LNG carrier traffic in the waterway would substantially contribute to stranding of Oregon Coast coho within Coos Bay.

Exotic, Invasive Species by LNG Carriers

Invasive species have the potential to modify the food base and induce other ecological modifications in the estuarine area of Coos Bay. NAS are aquatic species that degrade aquatic ecosystem function and benefits, in some cases completely altering aquatic systems by displacing native species, degrading water quality, altering trophic dynamics, and restricting beneficial uses (Hanson and Sytsma 2001). Within the Coos Bay estuary, over 67 NAS have been identified (ANSTF 2006).

There are no current studies that evaluate the impact of introduced fishes on coho salmon (ODFW 2005). The introduced species, striped bass and shad, presents the highest risk of impact to coho salmon in the Coos Bay estuary (ODFW 2005). However, navigational dredging within Coos Bay has altered salinity levels, which may have impacted striped bass egg and larval survival, reducing numbers and threat of striped bass predation on coho (Moore et al. 2000).

Loaded with water from the surrounding ports and coastal waters throughout the world, ships can carry a diverse assemblage of marine organisms in ballast water that may be foreign and exotic to the ship's port of destination. If water were to be directly transported from port to port, which is not proposed, this transfer could result in aquatic biological invasions. Invasive species threaten to outcompete and exclude native species and the overall health of an ecosystem, causing algal blooms and hypoxic conditions and affecting all trophic levels resulting in a decline in biodiversity.

Potential new invasions of zebra mussel (*Dreissena polymorpha*), Chinese mitten crab (*Eriocheir sinensis*), and hydrilla (*Hydrilla verticillata*) can potentially affect Oregon Coast coho salmon. Other invasive organisms including varied plants, invertebrates, and other fish are also known to be detrimental to native Oregon Coast coho salmon (Stout et al. 2012). For example, Oregon Coast coho smolts during out-migration consume a mudshrimp (*Upogebia pugettensis*), the major food sources in Yaquina Bay (Stout et al. 2012). These intertidal benthic invertebrates have been dramatically affected by the recently introduced isopod parasite (*Orthione griffenis*), likely introduced from Asia in the 1980s (Dumbauld et al. 2011).

EPA developed specific requirements for ballast water treatment under the Vessel General Permit requirement under the CWA NPDES program to reduce the chance of releasing invasive organisms in U.S. waters in 2013 (78[7] Federal Register 121938 [April 12, 2013]). This regulation requires that beginning December 19, 2013, all newly built large vessels would be required to treat ballast water to kill potential invasive organisms, with older vessels of the size that would be used for the Project having some delay in implementation of this requirement (first scheduled dry dock date after January 1, 2016). Prior to implementing treatment of ballast water, the current BWE process is mandatory under the National Ballast Water Management Program all large vessels that would discharge ballast water within 200 miles of the U.S. coast would be required to exchange ballast water outside of this 200-mile area. This was originally established by Nonindigenous Aquatic Nuisance Prevention and Control Act of 1990 and further amended by National Invasive Species Act of 1996 and National Aquatic Invasive Species Act of 2003, amended in 2005 and again in 2007 (NEMW 2007).

The required treatment of water would ultimately be an improvement over the requirement to just exchange ballast water to “flush” potential invasive organisms outside of the 200-mile territorial waters of the U.S., which was reported to reduce organisms by 88 to 99 percent (NRC 2011). The new requirement for treatment level is to reduce most organism types to less than 10 living organisms per cubic meter of ballast water. While this requirement may not eliminate all risk of invasive species entering waters, it is a substantial measure that would reduce the risk of project actions introducing invasive organisms into waters of the project area. Several other regulations apply to ballast water management and discharge that would be followed by all LNG vessels; these regulations would also aid in both ensuring reduction of discharge of potentially invasive species and, through vessel inspections, that procedures are followed, as noted in section 3.1.1.3.

All ships utilizing the Port of Coos Bay are subject to the 2012 USCG Final Rule on Ballast Water Discharges. Pursuant to this Final Rule, in order to discharge ballast water into the slip area while concurrently loading LNG cargo, all LNG carriers are required to carry out an exchange of ballast water in waters beyond the EEZ, from an area more than 200 nautical miles from any shore, and in waters more than 2,000 meters deep, or utilize one of several USCG-approved Ballast Water Management (BWM) methods. It is expected that LNG carriers calling at the LNG Terminal will be required to exchange ballast water at sea, more than 200 miles offshore; therefore, the discharge of ballast water will comply with the 2012 Ballast Water

Discharge Standards and the potential impact for ballast water to introduce invasive species of interest in Coos Bay will be negligible.

ODEQ recently revised the Oregon ballast water regulations to make the Oregon regulations more stringent for vessels arriving from “low salinity ports” by requiring ballast exchange in addition to the current Federal ballast water treatment requirements. This applies to vessels that represents a ”high-risk” for the transport and release of aquatic invasive species arriving from “low salinity ports” (like those in Oregon). A “low salinity port” is defined as a port where ballast water salinity is less than or equal to 18 parts per thousand (or when the vessel operator is unable to verify ballast salinity). A “High Risk Voyage” is defined as voyages originating in the “low salinity ports” that represents a “high-risk” for the transport and release of aquatic invasive species arriving from such “low salinity ports.”

The new rules retain ballast water exchange requirements, in addition to meeting federal ballast water treatment requirements, for what is termed as “high-risk voyages,” i.e., those that have taken ballast from low-salinity environments. This is a measure to protect Oregon’s low-salinity ports during a period when the reliability of new “first generation” ballast water technologies are proven to be effective for low salinity ballast.

The ballast water discharged at the terminal would be that from 200 miles out in the open sea. Therefore, it is expected that current and future provisions apply both to the import and export of nuisance species, and by compliance with this Act and other regulations, the LNG carriers would not likely cause exotic nuisance species to be introduced into Coos Bay, U.S. waters, or the ports of destination of the LNG cargos. As a result, adverse effects on Oregon Coast coho salmon are expected to be unsubstantial.

Another potential source of invasive species, other than LNG carrier ballast water, is transfer between waterbodies by construction equipment used in water, or other water transfer actions. USGS (2017) identified two NAS that may occur within the Coos Bay estuary: New Zealand mud snails (*Potamopyrgus antipodarum)* and brackish water snail *(Assiminea parasitologica)*. PCGP would not obtain hydrostatic test water from either Coos Bay or the Coos River, to prevent the spread of NAS from the estuary to inland watersheds. PCGP currently has procedures in the *Hydrostatic Testing Plan* (see appendix U), which includes measures such as inspection and cleaning of all dredge and similar equipment prior to use intended to reduce or eliminate the chance of spreading invasive species.

Entrainment of Coho Salmon from Dredging

After a review of dredging studies done through 1998, Reine et al. (1998) concluded that “much of the available evidence suggests that entrainment is not a significant problem for many species of fish and shellfish in many bodies of water that require periodic dredging.” Dredge entrainment studies over a four-year period in the Columbia River found no juvenile or adult salmonids entrained during dredging, although some other pelagic fish were entrained (Larson and Moehl 1990). Juvenile salmonids also generally remain in shallower depths likely away from the typically deeper bottom dredge areas (Carlson et al. 2001) and dredging would occur when few or no rearing or migrating juvenile coho salmon would be present.

Entrainment and Impingement through Vessel Cooling Water Intake at the LNG Terminal

During operation of the LNG Terminal, vessels at LNG slip may entrain marine organisms including juvenile coho salmon through cooling water intake needed for vessel power plant operations. The quantity of cooling water used depends primarily on size and type of vessel, time at the terminal, and power source used while at the terminal, and amount of recirculation. LNG vessels would re-circulate water while loading LNG at the berth and the amount of cooling water to be re-circulated is a function of the propulsion system for the vessels. The details of the cooling water intake and flow amount are discussed in section 3.5.1.3 but based on assumptions estimated cooling water used for each LNG vessel, depending on vessel type while at the LNG Terminal is between 22 to 69.7 million gallons of cooling water recirculated to the Slip over a 24 to 26-hour loading cycle of LNG cargo.

LNG vessel sea chests are typically 3.5 to 4.2 square meters covered by a screen with 4.5 mm bars, spaced every 25 mm and approximately 15 to 20 feet above the channel bottom. Additional finer mesh screens are located internally on the vessels to prevent larger items from entering the system. These screens would not meet NMFS (1997c) screening criteria for juvenile salmonids. Smaller marine and estuarine fish, juvenile stages of crab and shrimp and other zooplankton, eggs, and larvae fish could also be entrained. Some estuarine organisms, potentially including juvenile salmonids, would be removed from Coos Bay with this process during every loading cycle. It is expected that a high portion of juvenile larval stages of fish and invertebrates entrained or impinged would suffer mortality. Nevertheless, natural mortality of these early life stages is extremely high. The result would be less than 1% of earliest life stages reaching adult size, with natural mortality more than 20 to 30% per day during the earliest growth periods (Comyns pers. comm. 2003). For example, data from an estuarine cooling water intake site determined that intake water larval stage entrainment had very low natural survival (Marine Research Inc. 2004). On a typical LNG carrier, the location of the water intake is near the inner portion of the slip at a depth of about 30 feet, and as a result, it is unlikely there would be an abundance of aquatic organisms in the intake area. Salmonids migrating in Coos Bay would more likely be swimming in the main channel, away from the shoreline and the inset slip, thus reducing their chance of encountering the LNG carrier intakes. Therefore, the off-channel, artificially-created marine slip at the LNG Terminal would probably have a lower presence of fish than the rest of Coos Bay, and the risk of juvenile salmonids becoming impinged or entrained in the LNG carriers' water intakes is expected to be low.

The estimated velocity at the opening of the cooling water intake for a steam propulsion system ranges from 2.2 to 4.4 feet per second (ft/sec) (0.66 to 1.3 meters/second), depending on the intake rate of cooling water used. The estimated velocity at the opening of the cooling water intake for a dual propulsion system is approximately 1.3 ft/sec (0.39 meters/second), depending on the intake rate of cooling water used. NMFS recommends an approach velocity for screening systems for salmonids of less than 60 mm is 0.33 ft/ sec, and 0.8 ft/sec for larger juvenile salmonids (NMFS 1997c). These guidelines also include other requirements such as sweeping velocity and type and size of openings that are not present on these screens. The result is likely to be that fish at least up to fry and possibly larger juvenile size salmonids including coho salmon near the intakes may be entrained or impinged during cooling water intake.

Loss of juvenile coho salmon could reduce adult coho salmon returns. NMFS (2008d) in their assessment of effects of loss of juvenile coastal coho salmon from local airport expansion assumed a 4 percent Coos Bay coho salmon smolts survived to return as adults. Even so, due to the extremely small portion of total water intake relative to the volume of Coos Bay, the relative portion of juvenile salmonids that would suffer direct mortality would be small. In the case of coho salmon, few would be as small as 60mm, as most would be outmigrating as age 1+ likely greater than 120mm. So, many of the juvenile coho salmon would actively be able to avoid being entrained or impinged at the unscreened intake. Also, the slip would be excavated from the current upland, located away from the main channel of Coos Bay, which may, depending on coho salmon distribution, reduce overall chance of coho salmon being in the vicinity of the LNG vessel intakes while at the terminal. This would reduce the chance of juvenile migrating coho salmon in the Coos Bay being in the vicinity of the intake. Actual distribution of juvenile coho salmon within the project area is unknown. However, juvenile salmonid studies in the lower Columbia River observed that juvenile coho salmon were in greater abundance away from shoreline areas often in deep water during their outmigration (Johnson and Sims 1973; Dawley et al. 1986; Ledgerwood et al. 1991). Carlson et al. (2001) found that in the lower Columbia River that less than 20 percent of all fish were found along the shore, with about evenly split between the channel and channel margins.

Based on the Columbia River studies coho salmon migrating to the ocean would likely be more closely associated with the main channels than the nearshore area and the inset slip, reducing their chance of encountering the intakes. While actual Coos Bay distribution is unknown available literature suggest relative abundance near the LNG carrier intake would be relatively low. Considering likely distribution of coho salmon relative to the vessel intake, size of juvenile coho salmon that would allow avoidance, and limited frequency and magnitude of cooling water intake, loss of coho salmon from entrainment would be slight.

Entrainment of Food Organisms

As noted above, entrainment of organisms, including plankton that are a source of food for juvenile coho salmon, would occur from water intake for LNG vessels. Food organisms used by juvenile estuarine coho salmon and other salmonids include a variety of taxa. Many forms of invertebrates including epibenthic and pelagic zooplankton (e.g., harpacticoid copepods, calanoid copepods, amphipods, and mysids), larval stages of other groups, and larval fish are known sources of food used by estuarine rearing stages of coho salmon.

Shanks et al. (2010, 2011) sampled zooplankton and icthyoplankton in Coos Bay near the LNG Terminal. The primary intent of these studies was to help characterize what food sources are present in the region of the water intake and the relative effect entrainment may have on these food sources. The sampling was intended to determine seasonal, tidal, and daily changes in abundance of zooplankton including larval fish, shellfish, potential salmonid prey organisms, and other miscellaneous zooplankton that may occur in the project area. A variety of zooplankton were found to be present within the bay (see table 3.5.4-13). Among the potential salmonid forage items, copepod adults, lavaceans, harpacticoid copepods, and Daphnia had the highest peak abundance. Overall, larval fish abundance was generally low, with those that spawn primarily in or near estuaries common (surf smelt, sand lance, and staghorn sculpins). At times, other larval or juvenile fish were relatively abundant including English sole, buffalo sculpin, anchovy, and pipefish. A total of nine fish species were captured (Shanks et al. 2011). Over 12 taxa of crab and shrimp larvae were also collected, including some recreational and commercially important crab and shrimp species, such as Dungeness crab and ghost shrimp larvae (Shanks et al. 2011).

TABLE 3.5.4-13

Taxa Groups Collected in Coos Bay Near the LNG Terminal during 2009–2011

Categories	Specific Taxa
Fish larvae/juvenile	Surf smelt, sand lance, staghorn sculpin, buffalo sculpin, anchovy, pipefish, English sole, gunnel, pricklefish
Crab/Shrimp larvae	Porcelain crabs, pea crabs, green crab (invasive), xanthid crabs, majid crabs, cancer crabs (e.g., Dungeness, rock crab), Lithodidae, Hippidae, Pagurid (hermit crabs), Callinassa (ghost shrimp), Sergestid shrimp, Pachygrapus crassipes (striped shore crab)
Gastropod and Bivalves larvae	Mytilus (mussels), Clinocardium (cockles), Bivalve juveniles, Gastropod juveniles
Larval Invertebrates	Barnacle nauplii and cyprids, Mytilus larvae, bivalve larvae
Cnidaria/ctenophore	Sea anemone, Hydroids, sea goose berry
Polychaete Worm Larvae	Marine worms
Salmonid Food Prey	Mysids, Amphipods, Isopods, Cumaceans, Copepod adults, Harpacticoid copepods, Calanoid copepods, Daphnia, Larvaceans, larval fish

Source: Shanks et al. 2010, 2011

To make a reasonable estimate of potential loss from cooling water intake, we compared the relative amount of water used while at terminal to the amount of water in the Coos Bay project area. There are several assumptions with this method; the three major ones are: 1) organism distribution would be similar in water used to that in the bay as a whole, 2) all organisms entrained would be lost to the system, and 3) no avoidance to entrainment would occur. In addition, the estimate of entrainment loss was compared to what typical natural mortality loss would be for invertebrate and vertebrate life stages that are common in zooplankton as potential salmonid food sources. This information provides a perspective of how entrainment loss may influence food supply relative to natural conditions. This approach was developed in the Shanks et al. (2010, 2011) documents.

The amount of water that would be used during one LNG vessel loading event, assuming no recirculation, is estimated to range from 82.5 to 263.8 thousand m^3 (22 to 69.7 million gallons) over the course of about 24 to 26 hours while the LNG vessel would be at terminal. The period at the terminal would span approximately two tidal cycles (each tidal cycle takes approximately 12 hours). An approximation of spring high tide water exchange in the Project vicinity over one complete high and low tide cycle is 122.5 million m^3 based on data from the SHN Consulting Engineers and Geologist, Inc., technical memo (see Shanks et al. 2010, 2011). Neap tides (tides that occur when the difference between high and low tide is least) are less; however, these were not directly measured. In their analysis of ballast water intake, Shanks et al. (2010, 2011) estimated the volume passing the Project during lower tidal levels to be 106 million m^3. Assuming tidal values would mostly vary between two ranges the average volume passing the LNG Terminal would be about 2 times 114.25 million m^3. Using the figure of 114.25 million m^3 for water in Coos Bay, it was estimated that from 0.07 to 0.23 percent of the water near the marine slip would be taken in for engine cooling while an LNG vessel is at terminal at the terminal based on average tidal exchange. Theoretically, organisms in this entrained water would be lost to the Coos Bay system and therefore not available as a food source.

The loss of these organisms from entrainment can also be compared to loss from natural mortality in the bay environment. Instantaneous natural mortality rate (per day) can be defined by the function: M = ln (N_0/N_t)/-t, where M is instantaneous mortality rate, and N_0 and N_t are the initial and final abundance of larval after time t (Rumrill 1990). The comparison between entrainment and natural mortality loss of potential larval food organisms was made assuming 100 percent mortality of all organisms entrained during water intake and all mortality occurred during a single day. Additionally, it was assumed that all pelagic zooplankton in the project area during water exchange on an average day (i.e., 114.25 million m^3) suffered one day's natural mortality at the rate determined in the literature.

Rumrill (1990) provides estimates of mortality rates for a variety of marine invertebrate larval and in some cases through juvenile stages. McGurk (1986) supplies similar information for a variety of larval stages of marine fish. These values provide the bases for comparison of potential Project entrainment loss to that from natural mortality. Rumrill (1990) supplied estimates of morality rate using two methods with different data sets. One set is based on the contrast between larval production and subsequent recruitment, and the other is based on the monitoring of larval cohort in the plankton. The lowest and average mortality rates from Rumrill (1990) and McGurk (1986) are shown in table 3.5.4-14 for invertebrates and fish larvae. Invertebrate 1 and 2 in this table refer to the two respective rate groups from Rumrill (1990). Average and lowest mortality rates data for larval invertebrates and larval fish from these two sources were similar. Average loss of organisms from entrainment during one LNG vessel loading cycle would range from 0.4 to 0.7 percent of what would occur from natural morality in one day. For the lowest literature mortality rate of larval taxa among those reported, daily entrainment loss would be much higher ranging from 0.7 to 1.8 percent depending on what water volume was used during one vessel loading cycle and which taxa group data are used. These values are conservative estimates when compared to natural mortality that would occur in the Coos Bay system overall because entrainment would not occur daily whereas natural mortality would.

Because about 120 round LNG carrier trips a year would occur, LNG loading and water intake use would occur on average every three days. Therefore, relative fish food organism loss from entrainment annually would be considerably less than that estimated. Overall reduction in food sources for marine predators from entrainment of planktonic organisms appears to be slight, considering various factors. On average, water intake would be less than 0.23 percent of the water passing the project on a daily tidal cycle, so relatively few organisms would be subject to entrainment assuming similar planktonic organism distribution at the intake. Typical "loss" on average would be about 0.7 percent or less of loss from natural mortality of invertebrate and fish larvae during the day of LNG cargo loading. Considering that LNG carriers would only be at the site and take on cargo every three days, the relative loss would be even less than this estimate. Overall, the loss of marine fish and their prey resources that may be utilized by coho salmon from entrainment, relative to numbers in Coos Bay, would be small and have unsubstantial effects on supply of coho salmon food resources.

TABLE 3.5.4-14

Comparison of Relative Loss of Larval Invertebrates and Larval Fish from Entrainment to Natural Mortality during Water Intake (Cooling) during One LNG Vessel Loading Event in Coos Bay, Oregon

Mortality Category in Literature Source	Taxa Group b/	Natural Mortality Rate M (daily)(M=ln(S)/-t) c/	Estimated Percent Loss from Entrainment Relative to Daily Loss from Natural Mortality a/	
			Low Intake	High Intake

Lowest	Larval Invertebrate 1	0.0305	2.5%	7.4%
Lowest	Larval Invertebrate 2	0.0161	3.6%	14.9%
Lowest	Larval Fish	0.0200	3.6%	11.6%
Average	Larval Invertebrate 1	0.1450	0.7%	1.7%
Average	Larval Invertebrate 2	0.2470	0.4%	0.8%
Average	Larval Fish	0.1969	0.4%	1.7%

a/ Values based on average daily Coos Bay tidal water exchange rate of 114,250,000 m^3, and one LNG vessel water intake of 82,500 m^3 (low) and 263,800 m^3 (high). Assumes 100% mortality of entrained organisms.
b/ Sources: Invertebrates from Rumrill (1990), and fish from McGurk (1986).

Temperature Effects in the Marine Slip from LNG Vessels at LNG Terminal

As previously discussed above for green sturgeon (section 3.5.1.3), the release of engine cooling water from LNG carriers at the terminal would result in warming the nearby water in the slip. Results of the modeling showed that for typical ambient flow conditions at a distance of 50 feet from the discharge point (LNG carrier sea chest), temperatures from dual fuel diesel electric LNG carriers would not exceed 0.3°C (0.54°F) above the ambient temperature. This difference would decrease with further distance. Based on estimated slip volume this total heat could result in an average water increase for the total slip volume during one day when the vessel is loading would range from 0.03 to 0.06°F. Additionally, no temperature effects would extend beyond the slip due to the much larger water volume of Coos Bay.

However, the slight increase in water temperature in the slip due to the release of engine cooling water while the vessel is at terminal would be ameliorated by cooling of the slip water during cargo load, due to the fact that LNG is at a temperature of -260°F. There would be a heat exchange between the cold hull of the vessel and the surrounding slip water, as discussed for green sturgeon above.

The results of the 2011 modeling described above were supplemented in 2017 with additional thermal plume modeling to investigate the extent of the regulatory mixing zone (RMZ) where cooling water discharge will be greater than 0.3 degrees Celsius above ambient (Moffatt & Nichol 2017g). The RMZ used in the temperature plume modeling is defined as the three-dimensional extent where water quality standards may be exceeded as long as acutely toxic conditions are prevented and fish habitat and other uses are protected. This modeling analyzed LNG carriers with capacity of 148,000 m^3 and 170,000 m^3. It also modeled cooling water discharges of 10 degrees to nearly 21 degrees Celsius into various ambient temperatures ranging from 8 degrees to 18 degrees Celsius and under constant and stratified salinity conditions. In summary, this latest modeling showed that the largest RMZ was associated with steam-driven carriers and extended up to 79.2 feet and 22.1 feet in longitudinal and transverse directions respectively, with a vertical rise of 12.1 feet under peak summer temperature conditions. Dual fuel diesel-electric driven carriers had a substantially smaller RMZ that extended up to 36.5 feet and less than 7 feet in longitudinal and transverse directions, respectively, with a vertical rise of up to 1.3 feet. In the future, LNG vessels will trend more to dual fuel diesel electric propulsion systems thereby reducing the total cooling water intake per vessel call (Moffatt & Nichol 2017g). It is unlikely that the water temperature of the slip would be greatly increased from the release of engine cooling water, therefore, no significant adverse impacts on aquatic species in the bay are anticipated.

Fish and invertebrates are adapted to function over the normal range of conditions encountered in their environment. Moderate to large temperature increases have the potential to reduce fish and invertebrate growth, reproductive success, and if high enough cause direct mortality. Fish of the north Pacific, including those found in Coos Bay, are adapted to cool water conditions and could be adversely affected by sharp large increases in water temperature. Temperatures over about 24 to 26°C (75.2 to 78.8°F) would be considered lethal in the short-term (a few days) for salmonids (WDOE 2002). The temperature of the water in Coos Bay undergoes both seasonal and diurnal fluctuations. In December and March, the ocean and fresh water entering the estuary had similar temperatures, around 50°F (10°C). In summer, low stream flows results in a rise of temperatures in the bay, to above 60°F (15.6°C) in September at CM 8 (Roye 1979).

It is expected that water temperature in the terminal slip influenced by engine water releases from an LNG carrier at the terminal is not likely to cause adverse impacts to coho salmon. First, engine cooling water released into the slip would only slightly increase water temperature for a limited distance away from the vessel. Second, the slight increase in water temperatures from engine cooling water releases would be offset by cooling from contact with the hull of a vessel loading LNG. Third, the volume of water in the slip and exchanges during tidal cycles would further minimize temperature variations.

Effects of Operational Lighting

Localized changes in light regime have been shown to affect fish species behavior in a variety of ways (Simenstad et al. 1999; Valdimarsson et al. 1997; Tabor et al. 2004, Nightingale and Simenstad 2001). Disorientation may cause delays in migration, while avoidance responses may cause diversion of migratory routes into deeper, less protected waters. In some cases, increased light may attract both predators and potential prey species (Simenstad et al. 1999; Valdimarsson et al. 1997; Tabor et al. 2004). Juvenile coho salmon show no response to moderately high light intensity, but become inactive in very low light (Hoar et al. 1957). Depending on their reaction, fish may have migration delayed, be moved into less protected deepwater habitat, or they may become more susceptible to predation, as light increases predators' ability to see fish and also may be attracted to the area.

Nighttime construction is likely to occur in the estuarine analysis area for in-water work activities such as dredging or placing revetment, as well as on-water activities such as receiving deliveries at the TMBB or MOF. Construction lighting will be designed, installed, and operated at a level that allows construction work to be completed safely and effectively while minimizing glare to surrounding areas. Construction lighting will be directed only to the surface waters of Coos Bay when necessary, in order to minimize impacts to aquatic organisms. Lighting for in-water work will be limited to the area around each vessel and the area of the in-water work. For example, during dredging, the area under the crane boom for clamshell dredging or derrick arm for cutter suction dredging will be lit. Lighting is anticipated to be a mix of fluorescent and sodium fixtures around the vessels (dredge, barges, tugs, and support vessels) with larger sodium or halogen lights shining on the work area (i.e., the water) under the crane boom or derrick of the suction dredge. Lighting for on-water work, such as barge or ship unloading, will be limited to the vessels and adjacent landing areas. Final marine construction lighting requirements will be subject to review and approval by the USCG as part of the Construction Security Plan.

Lighting at the LNG Terminal would likely include a mixture of low-power fluorescent lighting and higher intensity security lighting that would primarily be located on shore, in and adjacent to the slip. When an LNG vessel is not in the berth, the lighting would be reduced to that required for security. It would be focused upon the structures and not be in proximity to the water so as to serve as an attractant or deterrent to fish species. No high intensity lighting would be present near the water except possibly during vessel docking. When an LNG vessel is at the berth, it would physically block the lighting on the berth from the slip waters and, due to its proximity to the slip wall, would block the fish from getting too close to the lighting on the berth.

Lighting on the tug dock would be low intensity lighting for safety, providing sufficient light for personnel movements on the trestle out to the tug berth and for movement on the berth itself. There is no intention to provide lighting near the water line or high intensity lighting that would be associated with activities other than the simple berthing of the tugs at this location. The reduced lighting levels near the water would reduce or eliminate any behavioral effects to fish in the Project vicinity. The final details of the lighting arrangement would be determined through consultation with resource agencies including NMFS and ODFW to reduce potential adverse effects. Considering the limited distribution of the affected area, mitigation measures in place to reduce the light intensity, ample deep water adjacent to the affected area where fish could avoid lights at the LNG slip, and that final plans would be in place to further minimize light on water areas, adverse effects to Oregon Coast ESU coho salmon are not anticipated.

Acoustic Effects from Construction and Operation

Underwater noise may affect coho salmon. Noise from construction of the LNG Terminal and related effects on aquatic species in Coos Bay were previously discussed for green sturgeon. During construction and operation, noise would be generated by:

- excavation and dredging of the slip and access channel,
- installation of the open cell sheet pile bulkhead at the LNG berth,
- installation of the piles to support the LNG berth and tugboat dock,
- installation of land-based mooring bollard piles at the MOF face,
- installation of temporary mooring piles at the TMBB,
- installation of temporary dredge transport pipelines to the APCO Site, Kentuck Project, and Eelgrass Mitigation Site,
- installation of temporary mooring piles for booster pump and off loader barges used for Navigation Reliability Improvement dredging, APCO temporary work bridge piles, MOF fender piles,
- LNG vessel transit in Coos Bay, and
- general operations at the terminal.

These activities would generate underwater sounds pressure levels that could elicit some behavioral responses in aquatic organisms including fish.

The Fisheries Hydroacoustic Working Group (2008), a group including the FWS, NMFS, and the states of Washington, Oregon and California, has established recommended interim criteria for protecting fish from noise generated by pile driving of a peak level of 206 dB and cumulative level of 187 dB (fish greater than two grams) and 183 dB (fish less than two grams).

Construction air noise levels for the LNG Terminal are expected to be similar to typical commercial structure construction programs, which average from 47 to 57 dBA at 2,000 feet in the air (H&K 1994). Noise levels 50 feet air distance from typical construction equipment (not including pile driving, or sheet wall installation) to be used at the site would typically range from about 70 to 90 dB (see table 3.3.2-1 in section 3.3.2, Western Snowy Plover). Typical noise generated from operation would be less. Considering that noise levels would be attenuated from this equipment into water, based on the interim NMFS criteria, levels of noise that could cause direct adverse effects to fish would be unlikely from typical equipment and future operations.

Underwater noise may also be generated by driving sheet piles on land (dry piles) since some noise propagates through ground and sediments (especially through harder substrates such as rock and clay), and may transfer to the water column somewhere else (known as sound flanking). Sound in the water column would be at a lower level than at the source (WSDOT 2011a) because most sound energy does not travel through water but rather through the sediment. The potential effects of pile driving on land and in the water are discussed in detail in the green sturgeon section.

To summarize, injury to fish from peak sound pressure levels (206 dB in current guidelines) would occur up to 37 meters from the face of the MOF. Also, this study predicted that injury to both small (less than 2 grams) and large (greater than or equal to 2 grams) fish from cumulative sound exposure levels (183 and 187 dB respectively under current guidelines) would occur up to 1,723 meters from the shoreline. This distance was the same for both 10,000 and 20,000 total impact strikes because, in both cases, this was the distance when the noise attenuated to the sound level considered effectively quiet (150 dB). Under proposed guidelines (Popper et al. 2014), modeled distances to injury were considerably less, although the distance to temporary threshold shift (TTS) was the same – 1,723 meters. Based on the results of Wladichuk et al. 2018, installation of land-based piles at the MOF face would increase potential exposure of individual coho to underwater noise in an area encompassing the navigation channel from the MOF across the bay to the airport and southwest to the vicinity of Southport Lumber yard (Figure 3.5.1-2). These noise thresholds could be reached during pile driving of the 8 mooring bollards at the MOF that would take approximately 14 days to install. Individual fish occurring in this area during pile driving could experience physiological effects sufficient to cause injury.

Land-based pile driving at the MOF shown to generate injury-level in-water noise would be limited to the approved in-water work window, which is October 1 through February 15. This window would minimize risk of physical injury or disturbance to individual Oregon Coast coho that may occur in the Project vicinity during construction.

In addition to the large number of piles that would be driven on land, a smaller number of piles would be driven in the water column at various locations (e.g., TMMB, APCO site, etc.) that could create temporary noise levels sufficient to cause physical injury within approximately 300 feet of pile driving activities. These distances assume no sound attenuation (e.g., bubble curtain, cushion blocks, etc.). In-water pile driving would be limited to the approved in-water work window for the Project, which is October 1 through February 15. This window will minimize potential interaction with Oregon Coast coho juvenile rearing and outmigration through the estuary.

For vessel traffic and dredging activities, the intensity of the sound pressure levels can vary considerably. However, sound pressure levels are generally in the range of 112 to 160 dB, intensities that may influence organism behaviors or perceptions but are not great enough to cause physiological damage (Richardson 1995; Hastings and Popper 2005; Fisheries Hydroacoustic Working Group 2008).

It is expected that LNG carrier noise in Coos Bay would be less than in the marine analysis area as vessel speed would be greatly reduced, which affects the magnitude of sound levels. In the Hatch et al. (2008) study, an LNG carrier during travel produced sound levels (with one standard error) of 182 ± 2 dB re: 1 µPa at 1 meter that attenuated to 160 dB at 35 ± 11 meters and to 120 dB at 16,185 ± 5,359. Other than possibly values within one meter (3.3 feet) of the vessel hull, these are all values less than the current interim noise levels for fish noted above. Some dredging activities may generate noise levels that may be harmful to very small fish close to the activity. Fischer (2004) noted dredging source dB levels of 172 and 185 at one meter (3.3 feet) from the dredge. The upper range of these values exceeds the interim noise criteria for small fish (those less than two grams). Small fish very near the dredging (within about a meter) may be harmed if they remained in the area for a period of time. Initial slip dredging will involve some sediment removal from shallow water. Since dredging would occur during a period of low fish abundance, with few rearing juvenile coho present, it is expected coho salmon would rarely if ever be in a zone considered directly hazardous from noise levels.

Generally, response to noise impacts would be behavioral and perceptual, and not physiological in nature, as fish would tend to avoid the area during periods of high noise output. Underwater noise generated during on land construction and operation, ship noises from LNG carriers within the estuarine analysis area, and dredging in Coos Bay are all not expected to adversely affect coho salmon. It is expected that construction and operations noise would not have substantial adverse effects on aquatic resources including Oregon Coast coho salmon.

Habitat Effects – Slip and Access Channel

The construction of the LNG Terminal marine slip and access channel would impact local aquatic resources by removal or conversion of some habitats. About 36.7 acres of current upland habitat would be converted to open water, primarily deep subtidal habitat, during construction of the marine slip. Development of the LNG Terminal access channel and MOF would affect about 39.8 acres of estuarine habitat. About 14.76 acres of intertidal to shallow subtidal habitat, including 1.9 acres of eelgrass habitat and 0.06 acre of salt marsh, would be permanently modified to primarily deep subtidal habitat during the dredging process of the deepened channel.

Eelgrass habitat supplies a diverse habitat for fish (Murphy et al. 2000) and is thought to supply salmon fry with food and cover from predators (Simenstad 1987 and 1994). Generally, increases in eelgrass are considered to result in increases in juvenile salmon, including coho salmon (Plummer et al. 2012). Eelgrass is an important ecological component in Coos Bay affecting many species. For example, submerged aquatic grasses are important habitat for small prey species of adult lingcod (in Appendix B-2 of PFMC 2008). Submerged grass meadows provide cover and food for a large number of organisms including burrowing, bottom-dwelling invertebrates; diatoms and algae; herring that deposit eggs clusters on leaves; tiny crustaceans and fish that hide and feed among the blades; and, larger fish, crabs and wading birds that forage in the meadows at various tides. Eelgrass provides shelter for a variety of fish and may lower predation, allowing more opportunity for foraging. The protective structure attribute of eelgrass is primarily for smaller organisms and juvenile life history stages of fishes. Previous studies (Akins and Jefferson 1973) have reported that Coos Bay has 1,400 acres of lower intertidal and shallow subtidal flats covered by eelgrass meadows.

The dredging operation would change physical conditions of the bottom, locally altering the bathymetry and potentially altering the morphology and water currents. Benthic and epibenthic invertebrates that presently inhabit shallow intertidal and subtidal regions within the boundaries of the access channel would be removed with the dredged material. Ghost shrimp and sand shrimp (adults, juveniles and larvae), amphipods, clams, Dungeness crab, and various fish species are important prey for Oregon Coast coho. Therefore, the loss of invertebrates and vertebrates at the access channel would result in a reduction in fish food available to coho salmon in those areas affected by the Project in the short-term. However, the resulting deeper, less diverse habitat would likely be less productive for benthic food sources, and juvenile coho salmon are less likely to forage on benthic resources at these deeper depths.

As noted above the CHE (2011) modeling indicated during LNG transit, bottom disturbance from high bottom velocities would occur. This could result in some benthic organisms (potential coho salmon prey) being disrupted and some sediment would be moved during arrival and departure. Mobile organisms (e.g. crabs, shrimp) would be able to return to the region, while some benthic organisms may be permanently displaced. Turbidity would likely be slight due to the coarse characteristics of the navigation channel sediment that is resistant to current induced suspension. Overall, some loss of benthic organisms may occur from LNG vessel propeller wash during each transport trip near the slip approach, but the magnitude would be small and likely less than currently occurs under each existing large vessel trip.

The CHE (2011) report also modeled velocities and likely effects on sediment scour at the docking facility from the tugboat pushing of vessels to the terminal. Assuming very high power use by the tug to dock the LNG vessel, the model estimated maximum velocity on the far bank (about 275 feet from the propeller) would be mostly less than 2.0 ft/sec, which would be unlikely to erode the bank. Furthermore, this area would be armored so no erosion would occur. Near the bottom, maximum velocity in the docking channel would be about 2.16 ft/sec. Sediment analysis suggests that over 95 percent of the bottom material (mostly silt/clay size) in the docking channel would be susceptible to suspension at this velocity. The report also estimated that bottom scour would be limited to about two inches over a limited bottom area (approximately 100 by 50 feet) in the docking channel. Some bottom disturbance would likely occur during docking. In most cases, this disturbance is likely to be much less than estimated because of the conservative assumptions used for this model.

Overall while some sessile benthic and fewer mobile organisms may be displaced during boat transit in the main channel and landing within the docking channel, the limited occurrence and magnitude of bottom disturbance and sediment suspension would result in unsubstantial area organism effects and therefore no marked reduction in potential food sources for Oregon Coast coho.

As noted above, benthic communities in Coos Bay inhabiting mud substrates recovered to pre-dredging conditions in four weeks following typical channel dredging (McCauley et al. 1977). However, recovery in estuarine channel mud has been reported to be typically six to eight months (Newell et al. 1998). In the lower Columbia River, McCabe et al. (1997, 1998) noted benthic organism recovery in three months. Complete recovery may take longer than four weeks but would likely still be short-term. Since most juvenile coho are not present in Coos Bay until the spring outmigration period, and dredging would occur in fall to winter, many benthic food organism would be recovered in the dredged area prior to their arrival, limiting effects of organism loss to coho salmon. However, because of the large quantity being dredged and increased depth, it may take a longer period relative to typical dredging. This likely would result in short-term adverse effects to the benthic community and potential food resources for Oregon Coast coho salmon. Potential long-term effects of habitat modification would be offset by replacement of shallow water habitat, including eelgrass beds, in other portions of the Coos Bay (see section 3.5.4.4, Conservation Measures).

Shading Effects

Shading from over-water structures reduces the amount of light available to phytoplankton and aquatic macrophytes. However, the area where shading LNG Terminal facilities would occur is intended for industrial uses and not the creation of new habitat. The general habitat in the slip's region would not be conducive for many marine resources because of depth and steep rip/raped armored banks, so relatively few resources would likely utilize this newly created area. The water areas within the slip are being created from upland areas and therefore shading of currently un-shaded habitat would occur, and no net loss in productivity due to shading would occur. Project components that potentially could shade the new open water created by the construction of the slip include:

- The tug dock would be built over an open water portion of the newly developed slip and it would generally be about 470 feet long by 18 feet wide. In addition, there would be 360 feet of 8-foot-wide floats for mooring and accessing the security vessels.
- The tug dock would be connected from shore by a pile-founded trestle.

Most fish, including coho salmon, have developed countershading as an adaptation to avoid predation (Moyle and Cech 2000) from above (dark dorsal surface blends with bottom substrate) and from below (light ventral surface blends with light from the surface). Fish within a shaded area would be more easily detected by a predator, especially from below because light colored ventral surfaces would stand out against a shaded water surface. Predation potential, based on some observed fish behavior, is a concern (Nightingale and Simenstad 2001). However actual increased occurrence in predator numbers from even substantial overwater structures has rarely been documented. Additionally review of many marina and pier studies have not documented actual increased predation at these facilities (Nightingale and Simenstad 2001). For example, marine marina studies have found no documentation of increased concentrations of juvenile salmonid predators and some predators such as birds may be of lower abundance than under natural shoreline conditions (Cardwell et al. 1980, and Heiser and Finn 1970, as cited in NMFS 2005c). The extent to which any of these predators affect juvenile or adult coho salmon in shaded areas created by the proposed action is unknown, however, the probability of this occurring is low since it shades less than one percent of the slip surface area and the dock is located at the north side of the slip.

Kentuck and Eelgrass Mitigation Sites

There would be short-term localized impacts to aquatic resources to construct the Kentuck Project and Eelgrass Mitigation. Kentuck Project construction activities would include transporting dredge material into the site and earthwork and civil infrastructure improvements to re-establish a connection with Kentuck Inlet and Coos Bay. Dredge material is currently proposed to be unloaded and hydraulically transported into the site through a Temporary Dredge Transfer Line from a Temporary Dredge Off-Loading Area located as close as possible to the site in a minimum 20 feet of water depth. The Off-Loading Area could include a hydraulic unloader on a deck barge, mooring/fleeting barges, and booster pump(s). The number of temporary piles and/or spuds required to moor barges would vary depending on actual equipment and configuration. Intake water for offloading operations may be drawn through self-cleaning fish screens sized to minimize fish entrapment. Infrastructure improvements would include: constructing a new bridge in East Bay Drive to allow tidal exchange between Kentuck Inlet and the Kentuck Project; improving the existing dike separating the site from Kentuck Slough; constructing a new muted tidal regulator (i.e., a "fish-friendly" tide gate) in the upper portion of the Kentuck Project to redirect a portion of Kentuck Slough flows into the Kentuck Project; and raising the profile of East Bay Drive and approximately 1,900 lineal feet of Golf Course Lane to be above the zone of tidal influence. A fish-friendly culvert or other structure would be constructed within Golf Course Lane to allow passage into the drainage above the former golf course irrigation sump pond. The earthwork and the majority of the infrastructure construction activities would be isolated from Kentuck Slough, Kentuck Inlet, and Coos Bay. Construction of the East Bay Drive bridge and muted tidal regulator would require in-water work and isolation measures. The new bridge and tide gate would be designed to meet ODFW and NMFS fish passage requirements. JCEP would continue to work with both agencies, as the designs progress, to address fish passage without impacting the current influx of salt water on adjacent properties. There would be a short-term increase in turbidity into Kentuck Inlet and Coos Bay when the connection is reestablished to the bay and while the site equilibrates (see section 3.1.4.3, Sedimentation and Turbidity Levels).

As part of the Eelgrass Mitigation, a shallow-water hydraulic dredge is proposed to be used to lower areas that are currently too shallow to support eelgrass. A Temporary Dredge Line would connect the dredge and Temporary Loading Area, which would be located as close to the site as possible in a minimum 20-foot water depth. The Loading Area is proposed to include deck barge, transport barges/scows and tug boats. As noted above, the number of temporary mooring pile and/or spuds would depend on equipment and configuration. Construction would occur during the ODFW in-water work window. Construction of the mitigation site would likely result in direct mortality of marine organisms and would temporarily elevate turbidity levels from dredging, as discussed in section 3.1.4.1, Direct Mortality of Marine Organisms, and section 3.1.4.3, Sedimentation and Turbidity Levels. The resulting habitat increase from the Eelgrass Mitigation site would provide benefits to the fish and marine organisms that utilize this habitat overall by increasing the natural cover and forage production in Coos Bay. It is likely that the increased habitat would offset the losses from the LNG Terminal site.

Suspended Sediment – HDD across Coos Bay Estuary and Coos River

Coos Bay would be crossed by two HDDs, one from MP 0.28 to MP 1.00 (West HDD), the other from MP 1.46 to MP 3.02 (East HDD). The Coos River (a tributary to the estuary) would also be crossed using HDD at MP 11.13. At that location, the Coos River is under tidal influence and is addressed here in the estuarine analysis area rather than in the riverine analysis area. An HDD involves drilling a pilot hole, then enlarging that hole through successive reaming. High pressure drilling fluids, usually consisting of a slurry made of bentonite clay mixed with water, would be jetted at the drill head to advance the hole. Pipe sections long enough to span the entire crossing would be staged and welded along the construction work area on the opposite side of the waterbody, hydrostatically tested, and then pulled through the drilled hole. The right-of-way between the entry and exit hole of an HDD would generally not need to be cleared or graded, except for the area of the guide wires. Additionally, direct impacts on the waterbody, adjacent riparian vegetation, and associated aquatic resources would be avoided through an HDD. An HDD should not result in an increase of suspended sediments into the stream crossed, unless there is an "inadvertent return" or release of drilling mud, as discussed below.

The horizontal crossing length of the West HDD would span 5,192 feet, extending from the North Spit to the southeast, crossing the Coos Bay navigation channel and terminating at North Point in North Bend, Oregon. The HDD profile would pass approximately 158 feet below the railroad trestle bridge and approximately 138 feet below the deepest part of the navigation channel. The depth and the locations of the railroad trestle foundations are unknown at this time (GeoEngineers 2017a). The feasibility analysis for the West HDD anticipates a relatively low risk of hydraulic fracture and drilling fluid surface releases occurring along most of the HDD alignment during construction. However, there would be a high risk of hydraulic fracture and drilling fluid surface release within about 150 feet of either end of the HDD due to the anticipated loose sand and decreased depth of cover. Installation of an oversized casing may be needed at both ends of the HDD path to assist in efficiently transferring axial loads to the drill bit, and to mitigate against hydraulic fracture and drilling fluid surface releases within the loose sand anticipated in the upper 30 feet (GeoEngineers 2017a).

The horizontal crossing length of the East HDD would span 8,972 feet extending from North Point in North Bend, Oregon eastward across Coos Bay and ending at the mouth of Kentuck Slough. Surface conditions at North Point at the west end of the HDD consists of a relatively flat ground surface covered with fill stockpiles. The east end of the HDD is located within a flat grass vegetated area in Kentuck Slough Valley. The proposed depth of the pipeline would be 210 feet below ground surface.

For this HDD design, GeoEngineers (2017a) anticipates that it would be completed using pilot hole intersect methods, due to the substantial length. Because this crossing would be completed using pilot hole intersect methods, both ends are identified as entry points. For this design, the carrier pipe would be strung and fabricated along the Kentuck Slough valley floor on the east end of the crossing. The proposed carrier pipe stringing area would be located northeast of the east entry point along the Kentuck Slough valley floor. Kentuck Slough and Kentuck Way limit the available pipe string length to 5,293 feet so a tie-in weld will be required during pullback operations. The orientation of the HDD alignment would require two horizontal curves in the pull section, making fabricating and handling the pipe more difficult.

Drilling fluid containment would be achieved via relatively small fluid containment pits excavated adjacent to the entry points of the drill. These pits typically measure approximately 6 to 10 feet square and 4 to 6 feet deep. During drilling operations, drilling fluid returns and cuttings from downhole flow into the pits where the fluid is then pumped to a recycling system where most of the cuttings are removed and the drilling fluid can be recirculated downhole (GeoEngineers 2017a).

Because of the length of the HDD, there would be an increased risk of drilling fluid surface release during reaming operations. This risk can be reduced by reaming the hole from both ends of the crossing. This methodology helps reduce downhole annular drilling fluid pressures by shortening the flow path of the drilling fluid through the hole. Although this increased risk does not necessarily affect the technical feasibility of the proposed HDD, reaming from both sides of the crossing could potentially have cost impacts that may require consideration. In general, GeoEngineers (2017a) expects the risk of drill hole instability along the HDD drill paths to be relatively low. Minor hole instabilities may be encountered within the very loose to loose soils expected along the upper portions of the HDD profile at the east end near Kentuck Slough, but that condition would not jeopardize the successful installation of the product pipe. If hole instabilities are anticipated within the shallow portions of the drill profiles, large-diameter casing can be installed through the tangent sections of the drill profiles to stabilize those areas.

According to GeoEngineers' design (2017b) for construction using HDD across the Coos River (see appendix E), the design length of the Coos River HDD crossing would be approximately 1,602 feet. The proposed entry point would be located approximately 500 feet from the north bank of the Coos River and the exit point would be approximately 630 feet from the south bank. The entry and exit points would allow for adequate depth beneath the Coos River. The preliminary design would provide a minimum of 50.3 feet of cover below the Coos River. GeoEngineers' evaluation determined that the construction of the Coos River HDD crossing is likely feasible. GeoEngineers opined that there is a relatively high risk of hydraulic fracture and drilling fluid surface releases on upland sites along the first 500 feet and last 300 feet of the HDD, respectively. However, the risk of drilling fluid surface release to the Coos River would be relatively low. As is typical with all HDDs, the risk of drilling fluid surface release becomes high within approximately 150 feet of the exit. Drilling fluid surface releases may occur within these high risk zones even if the contractor maintains drilling fluid returns during construction and also maintains drilling fluid properties that are conducive to cuttings removal and formation of a "wall cake" to help stabilize the borehole and limit fluid interaction between the borehole and surrounding soils (GeoEngineers 2017b).

Inadvertent Release of Drilling Muds (Inadvertent Return)

The HDD installation method is considered an effective technique for avoiding in-stream impacts by eliminating the need for in-stream excavation (Reid and Anderson 1998; Reid et al. 2004). Even with this technique, there is a potential for impact as a result of the HDD process. Drilling requires use of a drilling mud for lubrication of the bit and removal of cuttings. A non-toxic, biodegradable bentonite clay mixture makes up drilling mud. Because the drilling mud is under pressure during drilling, if the bit encounters substrate fractures or channels, it is possible for bentonite to escape from the hole (termed an "inadvertent return"). Bentonite can escape to the surface through fractures in the drilled substrate.

While bentonite by itself is generally considered a non-toxic drilling mud (Breteler et al. 1985; Hartman and Martin 1984; Sprague and Logan 1979), Reid and Anderson (1998) indicate the toxicity of bentonite (sodium montmorillonite) in fresh water ranges from 5,000 to 19,000 ppm (mg/liter) based on 96-hour tests for LC50 (the concentration at which 50 percent of the test population dies after 95 hours of exposure) on rainbow trout. The toxicity classifications based on LC50 values ranged from "slightly toxic" (5,000 ppm) to "practically non-toxic" (19,000 ppm) (Reid and Anderson 1998). In other tests, toxicities to lake whitefish and rainbow trout demonstrated threshold concentrations of 16,613 and 49,838 ppm (mg/l), respectively (Reid and Anderson 1998). More recently, toxicity to rainbow trout (LC50, 96-hour) was reported to be 19,000 mg/l (ClearTech 2015). LCD50 concentrations >10,000 ppm would be considered "practically non-toxic". In marine water, a 96-hour LC50 bioassay for toxicity of bentonite on a mysid shrimp (*Mysidopsis bahia*) was >1,000,000 ppm (Reid and Anderson 1998).

Bentonite, as with any fine particulate material, can interfere with oxygen exchange by the gills of aquatic organisms (EPA 1986). The degree of interference generally increases with water temperature (Horkel and Pearson 1976). Impacts would be localized and would normally be limited to individual fish in the immediate vicinity of the inadvertent return. The majority of highly mobile aquatic organisms, such as fish, would be able to avoid or move away from turbidity spots and plumes (Reid and Anderson 1999). Short-term pulses of suspended sediments (sharp increases within an hour) disrupt the feeding behavior and dominance hierarchies of juvenile coho salmon and elicit alarm reactions that may cause fish to relocate downstream to undisturbed areas (Wilber and Clarke 2001; Berg and Northcote 1985). Other less mobile or immobile organisms, such as clams, mussels and other macroinvertebrates, would incur direct mortality (Wilber and Clarke 2001). Bentonite can smother macroinvertebrates and adversely affect filter-feeders (Falk and Lawrence 1973, Hair et al. 2002, and Land 1974 in Cameron et al. 2002). Bentonite can also exacerbate or enhance the effects of toxic compounds to fish and aquatic invertebrates if those compounds are present in aquatic habitats (Hartman and Martin 1984). Similar to other fine-grained particulates, bentonite in flowing water is more likely to remain in suspension longer than in standing water. Consequently, effects to coho salmon by a release of bentonite into a waterbody would ultimately depend on volume of the release, volume of water present, and current.

Dispersion of drilling fluids from a release site (inadvertent return) is a function of the energy, salinity, and sediment transportation characeristics of the watercourse and the amount of fluid released. In low-flow areas such as tidal mudflats, releases will exhibit limited horizontal transport. If drilling fluid is released into Coos Bay, the drilling fluid will not likely mobilize as it would in a rapidly moving river (Reid and Anderson 1998). Coos Bay is relatively shallow throughout much of the HDD alignment. The mudline becomes exposed during low tides across much of the alignment except within the dredged shipping channel. In the event of a drilling fluid release into Coos Bay, the drilling fluid would likely settle onto the bay floor, where it could be contained and removed (Pacific Connector Gas Pipeline 2017). Since marine bioassays suggest bentonite to be non-toxic (Reid and Anderson 1998), a coating of bentonite on mudflats would most likely create a physical barrier to benthos burrows and interfere with species' feeding mechanisms, similar to existing depositional phenomena in the estuary. If drilling fluid is released into Coos Bay it would be addressed in accordance with the provisions of the containment plan (Pacific Connector Gas Pipeline 2017). It is expected that most drilling fluid released could be captured and cleaned up.

Reid and Anderson (1998), the Canadian Pipeline Water Crossing Committee (1999), and Reid et al. (2008) reported that 13 of 30 HDD stream crossings had drilling mud releases (citing Harder Associates 1996). The statistic is based on drilling mud releases during the early days of HDD technology (first conducted in 1971). The summary by Reid and Anderson (1998) that follows provides a substantive description of the causes of inadvertent returns and subsequent effects to streams and habitat in the cases drilling mud releases.

Drilling mud releases during HDD construction can result from:

1. Circulation losses through highly permeable gravels;
2. Mud migration along rock joints or fractures that intersect with the river bottom;
3. Loss of pilot hole directional control resulting in the intersection with the river bottom or approach slope;
4. Drilling mud pressures exceeding ground stress, widening existing or creating new fractures (hydraulic fracturing), allowing for mud migration;
5. Substantially different elevations of entry and exit drill locations. Resulting pressure head differences can cause substantial upland leakages of drilling muds once the drill bit nears the ground surface or when it breaks the surface.

Drilling mud releases may surface through river and streambeds, wetland bottoms, or at upland locations. The volume of mud released to the surface would depend on:

1. Porosity of the substrate transporting the mud;
2. Extent and size of the porous material;
3. Pressure exerted on the mud by the hydraulic system;
4. Viscosity of the mud at the time of exposure;
5. Whether mud circulation can be maintained.

Magnitude of effects by mud releases to fish, streams and habitat would depend on the following (page numbers referenced from Reid and Anderson, 1998):

1. Toxicity of the drilling mud components and additives (pages 57-59; also Table 1);
2. Increased sediment loads (page 59);
3. Effects to hydrological conditions that would cause poor conditions for wetland plant establishment and growth (pages 59-60);
4. Release into streams and rivers could cause increases in the downstream drift of stream macroinvertebrates (page 60);
5. Level of exposure to fish (e.g., concentration), duration of exposure , lifestage of fish present, timing of release, and ability of the watercourse to remove or incorporate the released muds without degrading existing habitats (page 61).

The report by Reid and Anderson (1998) summarizes the general effects, known or hypothesized, associated with drilling mud releases but does not provide specific effects associated with each of the 13 instances cited.

In the event an inadvertent return occurs into the river, drilling fluid would enter the waterway causing short-term, temporary water quality impacts downstream of the project area including sedimentation and turbidity. In the event drilling fluid is inadvertently released into the river, the behavioral avoidance response of Oregon Coast coho is presumed to be triggered within the immediate vicinity of the release and the fish are expected to return and utilize the affected area shortly after the inadvertent release has been halted. PCGP's *Drilling Fluid Contingency Plan for Horizontal Directional Drilling Operations* (see appendix D) describes how the drilling operations would be conducted and monitored to minimize the potential for inadvertent drilling mud releases. The HDD Contingency Plan also includes procedures for cleanup of drilling mud releases. If significant concentrations are found during monitoring as a result of a release, the following possible corrective measures would be taken:

1. Deployment of containment structures, if feasible, and removal of drilling mud from substrate and streambanks if possible.
2. Increase the drilling fluid viscosity in an attempt at sealing the point at which fluid is leaving the drilled hole. The drilling operation may be suspended for a short period (i.e., overnight) to allow the fractured zone to become sealed with the higher viscosity drilling fluid.
3. If increasing the drilling fluid viscosity is ineffective, lost circulation materials (LCM) may be introduced into the hole by incorporating them in the drilling fluid and pumping the material down-hole. The drilling operation may again be suspended for a short period (i.e., overnight) to allow the fractured zone to become sealed with the LCMs.
4. Depending on the location of the fractured zone, a steel casing may be installed that is of sufficient size to receive the largest expected down-hole tools for the crossing. This casing installation provides a temporary conduit for drilling fluids to flow while opening the remaining section of the hole to a diameter acceptable for receiving the proposed pipe sections. To alleviate future concerns with the steel casing after the HDD installation is completed, the casing is generally extracted from the hole prior to or just after completing the HDD installation. However, there have been instances when attempts at extracting the steel casing were unsuccessful.
5. In the event drilling fluid flow is not regained through the annulus of the drilled hole and a steel casing installation is not utilized, the HDD contractor may elect to install a grout mixture into the drilled hole in an attempt to seal the fractured zone. The down-hole drilling assembly is generally extracted, and the existing hole is re-drilled to the point at which it had previously been drilled prior to having encountered the loss of drilling fluid.
6. In addition, a grouting program may be implemented from the surface in the event that the installation of grout into the drilled hole is unsuccessful. This approach is only practical in areas where drilling rigs with vertical drilling capabilities can access the HDD alignment. If a surface grouting program is utilized, the HDD drilling assembly is extracted from down-hole. Multiple holes are then drilled vertically on either side and along the HDD alignment to allow for grout slurry to be pumped into the fracture zone where the drilling fluid had previously been lost from the drilled hole. This process can take several days to complete in order to insert the grout in a grid pattern that covers the full fractured zone, during which time the HDD operation is suspended. Upon completion of the surface grouting program, the HDD operation would resume and the pilot hole would be reestablished through the grouted formation.

In some instances, it may be determined that the existing hole encountered a zone of unsatisfactory soil material, and the hole may have to be abandoned. If the hole is abandoned, it would be filled with cuttings and drilling fluid.

Overall at the site of any inadvertent return, the amount of drilling mud released into a waterbody would be low. The HDD locations on the Coos Estuary and on the Coos River have a large volumes of water and swift flows, where the drilling mud would be diluted. If an inadvertent release of drilling mud from an HDD occurred on the Coos River, it would be expected to have minor short-term adverse effects to aquatic resources including coho salmon.

Direct and Indirect Effects – Riverine Analysis Area

Outside of Coos Bay, the Pipeline would cross 116 of the waterbodies in table 3.5.4-4 (summarized below in table 3.5.4-13). Dry open cuts would be utilized at 89 crossings, while the South Umpqua River would be crossed twice, once by a Direct Pipe (DP) technology at MP 71.3 and again by a diverted open cut at MP 94.7. Twenty-eight of the waterbodies summarized in table 3.5.4-13 would not be crossed by the Pipeline but are adjacent to the centerline and within the construction right-of-way. Blasting may be necessary to construct across 22 streams that would be crossed by dry open-cut methods (see Project Description) because the streambed of each is bedrock (see tables 3.5.4-4 and 3.5.4-15).

All affected waterbodies within the three subbasins and nine fifth-field watersheds that are within the range of Oregon Coast coho salmon ESU proximate to the Pipeline are included in table 3.5.4-15. There are 137 waterbodies included in the table, of which 51 are perennial, 80 are intermittent, three are estuarine (Coos Bay crossed twice and the Coos River), and three others are ponds, not crossed (see table 3.5.4-4, above).

TABLE 3.5.4-15

Proposed Pipeline Construction Methods for Crossing Waterbodies within Subbasins and Fifth-Field Watersheds Coinciding with the Proposed Pipeline Route and Coho in the Oregon Coast ESU

	Number of Waterbodies with Construction Method

a/ Bedrock streambeds would be crossed by dry open-cuts but may require special construction techniques to ensure pipeline design depth including rock hammering, drilling and hammering, or blasting. The need for blasting would be determined by the contractor and would only be initiated after ODFW blasting permits are obtained.
b/ Waterbodies within the construction right-of-way that would not be crossed.

The Pipeline would cross 43 waterbodies that are known or presumed to be inhabited by coho salmon in the Oregon Coast ESU (see table 3.5.4-2, above). Effects by the Project could occur to freshwater, in-water construction activities, terrestrial/riparian habitat modification, accidental spills or leaks of hazardous materials, and periodic maintenance of the Pipeline. Construction of the Project could directly and/or indirectly affect Oregon Coast coho salmon and critical habitat through one or more of the following pathways:

- interference with key life history functions for native species;
- acoustic shock from blasting pipe trench through bedrock streambeds ;
- underwater noise produced during use of a track hoe or impact hammer if fish are proximate to the construction site;
- suspended sediment (turbidity) generated during pipeline construction across waterbodies can adversely affect coho and aquatic habitats;
- inadvertent release of drilling mud during HDD construction;
- movement blockage during in-stream construction;
- inadvertent release of drilling mud during HDD construction;
- movement blockage during in-stream construction;
- salvaging fish that are entrained and/or entrapped;
- removal of riparian vegetation that can reduce shade (which could increase water temperatures), limit streambank stability, and affect recruitment of LWD;
- effects to aquatic habitats including freshwater stream invertebrates;
- hydrostatic testing and risk of test water entering streams;
- introduction and/or redistribution of aquatic nuisance species;
- mobilization of contaminated substances;
- accidental release of fuels and entry of other petroleum products into surface waters;
- risk of channel migration, avulsion, widening, and/or streambed scour;
- effects to hyporehic exchange and hyporehic zones;
- run-off from new permanent access roads, new temporary access roads, existing access roads and temporary extra work areas;
- run-off from contractor yards, rock source and disposal sites, and aboveground facilities; and
- application of herbicides to control noxious weeds near waterbodies may adversely affect coho.

Timing to Life History Functions

Within the range of Oregon Coast coho ESU, PCGP would avoid constructing across fish-bearing streams during periods of sensitive fish use. This construction window would typically occur in periods of lower flow rates in streams. The ODFW (2008) in-stream construction window for coastal tributaries, the Coquille River and tributaries, and tributaries to the South Umpqua River is July 1 to September 15. In-stream work within the South Umpqua River mainstem is permitted from July 1 to August 31.

In general, construction of the Pipeline would be timed to miss periods of major juvenile or adult migrations in freshwater based on allowed fishery construction windows, typically July 1 to mid-September for most streams, and some other dates for specific waterbodies. Timing of in-water work in aquatic habitats within the Coquille and South Umpqua subbasins would generally coincide with low flows and high water temperatures during summer and early autumn, discussed above in section 3.5.4.2 (see figure 3.5.4-4, Coos subbasin; figure 3.5.4-5, Coquille subbasin; and figure 3.5.4-6, South Umpqua subbasin). The in-stream construction windows could coincide with upstream adult migration by coho. Construction across waterbodies within the Coquille and South Umpqua subbasins would be completed before spawning (see figure 3.5.4-1). However, juvenile coho would be present and migrating adults might be present within waterbodies flowing at the time of construction. Juveniles rear for about 15 months in freshwater before migrating in spring to the ocean. Consequently, juveniles present would likely be limited to juvenile fry that are several months old from the current year's emergence.

Acoustic Shock

There are 22 waterbodies within the Oregon Coast coho ESU where shallow bedrock may occur where potentially necessitating blasting and/or mounted impact hammers be used to construct a trench through bedrock substrates (see table 3.5.4-4, summarized above in table 3.5.4-15). Explosives detonated near water produce shock waves that can be lethal to fish, eggs, and larvae by rupturing swim bladders and addling egg sacs (British Columbia Ministry of Transportation 2000). Explosives detonated underground produce two modes of seismic wave:, 1) body waves that are propagated as compressional primary (P) waves and shear secondary (S) waves; and 2) surface waves produced when a body wave travels to the earth surface and is reflected back (Alaska Department of Fish and Game - ADFG 1991). Shock waves propagated from ground to water are less lethal to fish than those from in-water explosions because some energy is reflected or lost at ground-water interface (ADFG 1991). Peak overpressures as low as 7.2 psi produced by blasting on a gravel/boulder beach caused 40 percent mortality in coho salmon smolts. Other studies revealed 50 percent mortality in smolts with peak overpressures ranging from 19.3 to 21.0 psi (ADFG 1991).

In 1991, the ADFG established a standard for blasting effects to anadromous fish that limited blast-induced overpressures in the water column. ADFG (1991) reported that a pressure change of 2.7 psi is the level for which no fish mortality occurs. ADFG (1991) calculated the straight line distances for a single shot explosive charge of given weight through rock and other materials to dissipate to an overpressure standard of 2.7 psi (non-lethal pressure for anadromous fish). Typical trench blasting scenarios use multiple 1- to 2-pound charges separated by an 8-milisecond delay to excavate the trench. With use of 1- to 2-pound charges in rock, the setback distance (at which 2.7 psi would occur) from the blast trench to the fish habitat is between 34 and 49 feet (see Table 3, in ADFG, 1991).

New research (Dunlap, 2009) and an in-depth review (Kolden and Aimone-Martin, 2013) of empirical studies of the physiological effects of blasting on adult salmonids and embryos prompted ADFG to revise the blasting standard (Timothy, 2013):

> *"The instantaneous pressure rise in the water column in rearing habitat and migration corridors is limited to no more the 7.3 psi where fish are present. Peak particle velocities in spawning gravels are limited to no more the 2.0 in/s during the early stages of embryo incubation before epiboly is complete."*

Application of the new standard for 7.3 psi in equations in ADFG (1991) was used to derive setback distances from water for 2-pound charges in rock. Based on these calculations, a distance of about 26 feet would result in the avoidance of adverse effects to salmonids in water. The setback distance used in PCGP's Fish Salvage Plan (appendix T) added 25 feet to each side of the construction right-of-way, totaling at least 50 feet from the blasting location at the trench. Application of the new ADFG blasting standard for a 2-pound charge in bedrock would indicate that the current setback distance is more than adequate to ensure that any blasting that does occur will not adversely affect ESA-listed coho salmon and other salmonid species.

Several approaches have been suggested to reduce risk of injury or mortality to fish in closest proximity to blasting locations (Wright and Hopky 1998):

- deployment of bubble curtains/air curtains to disrupt the shock wave;
- deployment of noise generating devices, such as an air compressor discharge line, to scare fish away from the site; or
- removal or exclusion of fish from the work area before the blast occurs.

To reduce impacts on resources, PCGP developed a *Blasting Plan* (see appendix C to the POD) with measures that incorporate many of these recommendations. The plan stated that PCGP does not anticipate conduction any in-water blasting in any streams crossed by the Pipeline. However, blasting may occur in uplands adjacent to streams, or within dry streambeds. In those situations, PCGP would attempt to minimize shock waves from blasting that may affect aquatic resources by the types of explosives selected, the size of charges, and the sequences of firing. In addition, bubble curtains may be used. The details of specific site blasting actions would be determined in coordination with managing resource agencies. Lastly, fish may be removed from the crossing area, in accordance with PCGP's *Fish Salvage Plan* (see appendix T and section 3.5.4.4, Conservation Measures below).

The *Fish Salvage Plan* includes measures to exclude fish and prevent them from re-entering isolated portions within waterbodies crossed for distances sufficient to avoid or minimize adverse effects by blasting bedrock in streambeds. The specific plans would be approved by the managing resource agencies. Prior to any blasting, proper permits would be obtained and agencies notified as required by permits.

Of the 22 waterbodies where shallow bedrock may occur potentially necessitating blasting and/or mounted impact hammers used to construct a trench, only 15 are known or assumed to support Oregon Coast coho: three in the East Fork Coquille watershed (tributary to East Fork Coquille River at MP 28.9, tributary to Elk Creek at MP 32.4, South Fork Elk Creek at MP 34.5); five in the Olalla Creek-Lookingglass Creek watershed (tributary to Shields Creek at MP 56.3, tributary to Olalla Creek at MP 57.1, tributary to Olalla Creek at MP 58.6, tributary to McNabb Creek at MP 60.1, McNabb Creek at MP 60.5); two in the Clark Branch-South Umpqua River watershed (Rice Creek at MP 65.8, Willis Creek at MP 66.9); three in the Myrtle Creek watershed (North Myrtle Creek at MP 79.1, tributary to North Myrtle Creek at MP 79.2, South Myrtle Creek at MP 81.2); and two in the Days Creek-South Umpqua River watershed (Fate Creek at MP 88.5, Days Creek at MP 89.6).

Dry open-cut construction, most likely by dam-and-pump procedures, would be used to cross 15 streams. At some waterbody crossing sites the right-of-way will be "necked down" to 75 feet; in others the construction right-of way would be the full 95-foot width. Fish would be salvaged from within the 75-foot or 95-foot wide right-of-way crossing of each stream by dry open-cut. The fish salvage area would be isolated by sand bag dams installed upstream and downstream from the centerline. As described in the *Fish Salvage Plan* (see appendix T), fish would be excluded from an area larger than the limits of the construction right-of-way width, isolated by sand bags. If basting is required, fish would be excluded from an additional 25 feet on each side of the construction right-of-way, an estimated maximum of 145 feet. Application of the new ADFG blasting standard for a 2-pound charge in bedrock would indicate that the current setback distance is more than adequate to ensure that any blasting that does occur will not adversely affect ESA-listed coho salmon and other salmonid species. The plan includes measures to exclude fish and prevent them from re-entering isolated portions within waterbodies crossed for distances sufficient to avoid or minimize adverse effects by blasting bedrock in streambeds.

Estimates of juvenile coho present in at crossing sites in streams were based on the following assumptions: 1) all rights-of-way are 95 feet wide at each stream crossing within which coho would be salvaged, and 2) coho would be excluded from an additional 50 feet (a total of 145 feet of stream length) from the right-of way edges (25 feet from each edge). Numbers of juvenile fry coho potentially present or assumed to be present in the streams with bedrock substrates are provided in table 3.5.4-16. Construction of the Pipeline through bedrock at those streams is likely to require blasting and the estimates in table 3.5.4-16 represent numbers of juvenile fry coho (195 juveniles expected) that could be displaced and or salvaged prior to blasting. The estimates in table 3.5.4-16 are based on no fish being herded out of the work area prior to dewatering (see *Fish Salvage Plan*). The actual number that would be salvaged is expected to be much less.

TABLE 3.5.4-16

Worst Case Estimates of Juvenile Fry Coho Present or Assumed as Present at Streams with Bedrock Substrates and Juveniles Salvaged Prior to Blasting During Construction of the Pipeline Project within the Oregon Coast ESU

Subbasin and Fifth-Field Watersheds	Dry Open-Cut w/ Juvenile Fry Coho Present	JuvenileFry Present at Each Crossing a/	Total Juvenile Fry Present b/	Juvenile Fry Salvaged at Each Crossing c/	Total Juvenile Fry Salvaged d/

TOTAL	**15**		**287**		**195**

a/ Juvenile Fry Present at Each Crossing based on Juveniles per Mile (see table 3.5.3-6) within a stream crossing length of 145 feet (95 feet construction right-of-way plus an additional 25 feet on each side, a worst case, see text).
b/ Total Juvenile Fry Present (worst case) = number of Juvenile Fry Present at Each Crossing multiplied by number of Dry Open-Cut crossings with potential for blasting and with Juveniles Coho Present.
c/ Juvenile Fry Salvaged at Each Crossing based on Juveniles per Mile (table 3.5.4-7) within a stream crossing length of 95 feet (worst case, see text), not salvaged within the additional 25 feet on each side.
d/ Total Juveniles Salvaged (worst case) = number of Juvenile Fry Salvaged at Each Crossing multiplied by number of Dry Open-Cut crossings with blasting and Juvenile Fry Coho Present. The estimate is based on no fish being herded out of the work area prior to dewatering (see Fish Salvage Plan in appendix T). The actual number that would be salvaged is expected to be much less.

Underwater Noise

Dry open-cut construction, more than likely dam-and-pump methodology, would be used at sites where blasting and/or mounted impact hammers would be required to construct a trench through bedrock substrates. Impulsive type sounds, sound generated by pile driving for example, create stress waves in the piling material that radiate sound through the surrounding media of substrate, air, and water and may propagate outward from the source through bottom sediment (Popper and Hastings 2009). Various studies have reported fish mortality, physical injury, auditory tissue damage, decreased viability of eggs, and decreased larval growth due to noise, mostly explosive blasts, seismic survey blasts, and air gun blasts (Hastings and Popper 2005). State agencies in Washington, Oregon, and California along with federal agencies have developed interim noise exposure threshold criteria for pile driving effects on fish (WSDOT 2011a; Fisheries Hydroacoustic Working Group 2008; Popper et al. 2006; and see discussion above in section 3.5.3.3 for coho salmon SONCC ESU). The threshold noise levels are assumed to be applicable to noise from a mounted impact hammer operating on bedrock substrates for 15 waterbodies potentially affected by the Pipeline project in the Coos, Coquille, and South Umpqua subbasins (see table 3.5.4-14, above).

Average maximum noise produced by mounted impact hammers due to impact on substrates (e.g., rock) has been reported at 90 dBA from 50 feet away in the air (see Table 7-4 in WSDOT 2011a). Using a simplified conversion of dB between air and water (see footnotes and discussion above in section 3.5.3.3 for coho salmon SONCC ESU) the noise produced by the impact hammer in air would be equivalent to about 182 dB re: 1 µPa @ 1 meter in water (see section 3.5.3.3 above for source impact hammer dB value). However, there is no information available to determine whether that noise level would be equivalent to peak sound levels or RMS levels, which are the basis for evaluating potential harm to fish, particularly related to cumulative sound exposure levels caused by multiple impact hammer strikes. However using the most conservative criteria (cumulative levels which assume multiple impacts over a short period), impact hammer values of 182 dB are at the limit of the current criteria considered to cause harm (183 dB; see section 3.5.3.3 above).

Further, the estimate of noise produced by in-water use of an impact hammer in any waterbody would be influenced by water currents, water depth, and bottom material and topography, as well as configuration and materials of the river banks. The effects of these factors are unknown (WSDOT 2011a). However, noise propagation in any waterbody, upstream and downstream from the construction site would be limited by the stream channels' sinuosity since the propagation is limited to straight-line distance from the source (WSDOT 2011a). Noise produced by impact hammers would be much reduced if construction does not occur within the water column, similar to reduction set back distances from the blast trench to the fish habitat to reduce blast overpressures to below 2.7 psi, discussed above.

Sounds produced by a mounted impact hammer operating in dry conditions might be conducted through bedrock substrate to approach the hearing threshold of fish, as for example the Atlantic salmon, which is around 90 dB re: 1 µPa (see Figure 3 in Hastings and Popper 2005). It is assumed that salmonids in the Pipeline project area at the time of construction would have hearing thresholds similar to Atlantic salmon. With that assumption, listed and non-listed salmonids present at the time of construction might detect the noise produced by an impact-hammer striking bedrock, but the noise is not expected to be of sufficient intensity to cause them injury as would SELs produced by pile driving.

When using the dam-and-pump stream crossing methodology, the typical right-of-way distribution of an isolated streambed (dry open-cut) would be no less than 25 feet on one side of the pipe trench and 50+ feet on the opposite side of the pipe trench depending on whether it is a 75- or 95-foot-wide crossing. Therefore, an area within the waterbody crossing equivalent to length of the blasting trench and approximately 25 feet wide (in the worst-case scenario) would be exposed to instantaneous hydrostatic pressure changes above 2.7 psi. In reality the distance in water affected outside of the 25 feet on land would be less than an additional 25 feet because water does not transmit energy pressure waves as well as rock (only about 70 percent of the distance away from the charge relative to rock, the most conductive substrate of pressure waves; see calculations in ADFG 1991), which the maximum distance is based upon. As noted above (see Acoustic Shock subsection) a fish salvage plan (see section 3.5.4.4, Conservation Measures below) is in place that would result in any fish present being removed from the area within this 25-foot potential effect area, eliminating potential noise effects from stream crossings.

There would be no in-water blasting; therefore, no in-water noise monitoring has been proposed. Procedures for conducting blasting in-the-dry have been provided in in appendix T, *Fish Salvage Plan*. Monitoring for efficacy of each stream crossing and fish salvage would be conducted throughout the entire process including function of upstream block nets to exclude fish from areas where they might be affected by blasting in the dry thus eliminating potential noise effects to fish during stream crossings. In situations where blasting would occur in uplands adjacent to streams or within dry streambeds, PCGP would attempt to minimize shock waves from blasting that may affect aquatic resources by the types of explosives selected, the size of charges, and the sequences of firing. In-air noise due to blasting would be mitigated in all noise-sensitive areas as described in PCGPs *Blasting Plan* (see appendix C to the POD).

Suspended Sediment by Pipeline Crossing Methods

Pipeline crossings of surface waterbodies would cause some downstream turbidity and sedimentation. The type of crossing and stream sediment characteristics can affect turbidity and suspended sediment in streams. All streams in the range of Oregon Coast coho salmon ESU would be crossed using the dry open-cut method (flume and dam-and-pump) (table 3.5.4-15), except those streams crossed by HDD, Direct Pipe (DP), or diverted open cut. Dry crossing methods including diverted open cut would result in minimal impacts, including temporary increases in suspended sediments in restricted areas. DP and HDDs would be installed without in-water work and would not directly affect the aquatic environment and associated species, except in the case of an inadvertent return during an HDD crossing, which could affect stream suspended sediment levels as discussed below.

Suspended Sediment – Dry Open Cut

Pipeline crossings of surface waterbodies would cause some downstream turbidity and sedimentation. The type of crossing and stream sediment characteristics can affect turbidity and suspended sediment in streams. All streams in the range of Oregon Coast coho salmon ESU, other than those crossed by HDD, DP, or diverted open-cut, would be crossed using the dry open-cut method (flume and dam-and-pump) (see table 3.5.4-15). Turbidity and sedimentation impacts from the dry open-cut methods are associated with: 1) installation and removal of the upstream and downstream dams used to isolate the construction area; 2) water leaking through the upstream dam and collecting sediments as it flows across the work area and continues through the downstream dam; 3) movement of in-stream rocks and boulders to allow proper alignment and installation of the flume and dams; and 4) when streamflow is returned to the construction work area after the crossing is complete and the dams and flume are removed. Both "dry" techniques produce much less sediment in the water than alternative "wet" open cut methods (Reid and Anderson 1999; Reid et al. 2002; Reid et al. 2004, Reid et al. 2008, Harper 2012). Therefore, if properly installed and maintained during construction and restoration, dry open-cut construction across waterbodies would produce minor levels of sediment and turbidity.

PCGP would minimize impacts on surface waters and aquatic resources by implementing the waterbody crossing and erosion and sediment control measures as described in its Pipeline project-specific ECRP. Actions described in GeoEngineers (2017d) would also be used to determine level of stream crossing risk. GeoEngineers, using a combination of field data and GIS data, rated proposed stream crossings based on the matrix along the entire route including 101 streams in the range of Oregon Coast coho. The matrix has two axes rating the crossing based on impact potential at the crossing and the relative stream response potential at the crossing. Each crossing was rated as low, medium, or high for each of the two axes (all stream crossings were placed into one of nine categories, such as Low–Low, Low–Medium, and Medium–High). Crossing 43 of the streams would warrant application of typical construction practices; crossing 33 of the streams would warrant typical construction practices with BMPs for sensitive streambed, banks, or riparian revegetation conditions to be determined by the EI during construction; crossing four streams would warrant typical construction practices with BMPs for sensitive streambed, banks, or riparian revegetation conditions to be selected by a qualified professional prior to construction based on site-specific information from pre-construction evaluation; and crossing one stream would warrant typical construction practices with enhancement BMPs such as rootwad enhancement for bank stabilization.

Construction across waterbodies would be completed as quickly as possible to shorten the duration of sedimentation and turbidity. If channels are dry during construction, small streams (less than 10 feet) are projected to be crossed in less than 24 hours, and intermediate streams (10 to 100 feet) usually in less than 48 hours. Times may be longer when flow diversion is required. Reid et al. (2004) noted that in flowing streams they monitored, in-stream work averaged 38 and 64 hours for dam-and-pump and flumed crossings, respectively. If circumstances required a construction delay, adequate site stabilization measures would be employed in accordance with the ECRP and permit conditions. However, failure of flow sealing and other in-stream structures at upstream diversions structures could occur from a variety of malfunctions such as pump failure, dam and flume failure, poor dam seal and others. Reid et al. (2004) noted seal failures of monitored diverted open cut crossing in one of 23 dam-and-pump projects and five of 12 for flumed projects. Should these occur, suspended sediment would be relatively elevated over those without failure, but immediate repair work could reduce the magnitude and duration of elevated suspended sediment. The effect on suspended sediment from planned dry crossings and unintended wet cuts crossings with repairs are discuss below in this subsection.

Alternatively, Harper (2012) modeled sediment entrained during wet open-cut pipeline crossings of 6 major (width >100 feet), 46 intermediate (widths >10 feet and <100 fee t), and 227 minor waterbodies (widths <10 feet) in New Hampshire. In addition, modeling included suspended sediment generated following dry open-cut crossing of intermediate and minor waterbodies but was restricted to a one hour period of duration associated with a "quick-flush" that occurs after a pipe is installed, the trench is backfilled, and water barriers, upstream and downstream from the workspace, are removed and turbulent, high energy flow across the backfilled trench suspends sediments which are expected to last for one hour (Harper 2012). The effect on suspended sediment from planned dry crossings and unintended wet cuts crossings with repairs are discussed below in this subsection.

Severity of Effects from Suspended Sediment

Salmonids exposed to moderate to high levels of suspended sediment for extended periods could be adversely affected. At high levels, turbidity directly affects survival and growth of salmonids and other species, interferes with gill function, and adversely affects substrate for egg development (reviewed and compiled by Bash et al. 2001). Turbidity can also reduce macrophyte cover (over the long-term) by limiting photosynthesis (Goldsborough and Kemp 1988), as well as adversely affecting fish vision, which is a requisite for social interactions (Berg and Northcote 1985), feeding (Vogel and Beauchamp 1999; Gregory and Northcote 1993), and predator avoidance (Meager et al. 2006; Miner and Stein 1996).

Salmonids may avoid areas of increased turbidity levels at 20 mg/l suspended sediment, and possibly lower concentrations depending on length of exposure (Newcombe and Jensen 1996). The elevated suspended sediment conditions would be short-term during pipeline installation and would not be continuous at any one location. This would reduce the chances of continuous elevated exposure for fish that may move little. Some other studies have found varied effects including lesser effects at these concentrations, with overall effects related to both duration as well as concentration (Newcomb and Jensen 1996).

Sediment stirred into the water column can be redeposited on downstream substrates, which could bury aquatic macroinvertebrates (an important food source for salmonids, and other fish in estuarine areas). Additionally, downstream fine particle sedimentation could affect spawning substrate habitat, spawning activities, eggs, larvae, and juvenile fish survival, as well as benthic community diversity and health (reviewed and compiled by Bash et al. 2001). Because the effects of increased sedimentation and turbidity are often limited to the period of in-stream work, the duration of these effects are usually relatively short. However, specific site characteristics including flow, substrate composition, relative disturbance and other factors could make the duration of construction effects last longer. One long-term study (during construction through three years after construction) of multiple pipeline crossings of coldwater streams found no measurable effect to fish or benthic resources or their habitat within 2 months to 3 years of construction (Blais and Simpson 1997) and Gartman (1984) reported rapid recolonization of benthic organisms on 30 pipeline projects post-construction.

Dry open-cut construction methods have the potential to alter fish abundance over the short-term. Reid et al. (2002) found that fish abundance downstream of dam-and-pump or flumed crossings reduced immediately after construction in two of four sampled sites. Mean sediment concentrations during construction at these four sites were all less than 100 mg/l (range 8 to 86 mg/l). Two sites sampled one month later had downstream reductions in fish abundance including brook trout. However, Reid et al. (2002) concluded, based on limited physical sediment-related stream changes, observed differences in fish abundance for most sampling were likely the result of factors other than project-generated sediment, such as low flow generated from water diversion actions and fish sampling methods. One year after construction, Reid et al. (2002) found no difference in fish abundance below these two sites from preconstruction levels.

Newcombe and Jensen (1996) compiled research from many sources that demonstrate effects to anadromous and resident salmonids by various levels of suspended sediment and exposure over time. This modelling process is used to assess the possible effects to salmonid resources in the project area from in-stream pipeline construction based on estimates of sediment concentration exposure duration. The developed models that approximate the level of effect is based on known levels of suspended sediment concentration and duration of exposure to that concentration in a stream. In order to use these models to estimate effects to salmonids, an estimate of these two parameters is needed.

Output from each model provides SEV scores that are summarized below. Values range from 0 to 14, where an SEV of 0 indicates no effects, an SEV between 1 and 3 indicates behavioral effects, an SEV from 4 to 8 indicates sublethal effects, and an SEV from 9 through 14 indicates lethal and paralethal effects (see Table 1 in Newcombe and Jensen 1996).

Behavioral Effects SEV scores

1 = Alarm reaction
2 = Abandonment of cover
3 = Avoidance response

Sublethal Effects SEV scores

4 = Short-term reduction in feeding rates and/or feeding success
5 = Minor physiological stress (increase coughing rate and/or increased respiration rate)
6 = Moderate physiological stress
7 = Moderate habitat degradation; impact on homing
8 = Major physiological stress; long-term reduction in feeding rate- feeding success; poor condition

Lethal and Paralethal Effects SEV scores

9 = Reduced growth rate and/or delayed hatching and/or reduced fish density
10 = 0 to 20 percent mortality and/or increased predation and/or moderate to severe habitat degradation
11= >20 to 40 percent mortality
12= >40 to 60 percent mortality
13= >60 to 80 percent mortality
14= >80 to 100 percent mortality

SEV scores are complex interactions of TSS concentrations and time of exposure to those concentrations where higher concentrations and longer exposures result in higher SEV scores and greater impact to fish. Effects of high concentrations may be ameliorated by brief exposures and conversely effects of low concentrations may be exasperated by prolonged exposures. In the analyses, downstream effects of TSS are primarily caused by very fine sand, silt and clay particles; coarser sediments settle out of suspension over relatively short distances downstream, closer to the crossing site. Specific information about each waterbody crossing is required to predict amounts of suspended sediment that would be generated, transported, and deposited downstream. That information includes: 1) stream width and depth, 2) water velocity, 3) streambed roughness, 4) grain size of excavated materials, and 5) background (ambient) levels of suspended sediment (Reid et al. 2008). Once total suspended sediment (TSS) concentrations generated by in-stream activities have been determined, they are applied in the dose-response assessments of sediment exposure, the SEV models by Newcombe and Jensen (1996).

Estimates of Likely Effects from Suspended Sediment

Average Channel Characteristics. PCGP incorporated site data, regional data, and available literature based models to provide an estimate of both suspended sediment levels and extent of effects to Oregon Coast coho salmon ESU from construction across streams. Specific channel characteristics for streams crossed by the Pipeline are not available. However, data provided in the ODFW (2014c) stream surveys included bankfull channel widths, bankfull depths, and stream gradients, in addition to substrates (Sand-Silt-Organics) noted in table 3.5.4-10a and table 3.5.4-10b above, for multiple streams within fifth-field watersheds crossed by the Pipeline (table 3.5.4-17). Those data were used to develop stream channel characteristics in each fifth-field watershed crossed that are assumed to apply to the actual streams that would be crossed in each of the watersheds.

TABLE 3.5.4-17

Channel Conditions for Streams Sampled during the Aquatic Habitat Inventory (ODFW 2014c) in Nine Watersheds within the Oregon Coast ESU that would be Crossed by Pipeline Project

a/ Stream-specific values are provided in appendix Y.

Estimates of Bankfull Flows. Sediment transport in streams depends, in part, on stream channel characteristics. Stream-specific values that were averaged in table 3.5.4-17 were used to determine stream discharged rate (Q) and water velocity (V_A). Manning's Formula (Limerinos 1970; Arcement and Schneider 1989) was used to estimate Q, the stream discharge rate (cubic meters per second, meter^3/sec):

$$Q = A\ (k/n)\ (R^{2/3})\ (S^{1/2})$$

with estimates of A, the cross-sectional area of a stream (square meters); R, the hydraulic radius (meters, where R = A/P, and P is the wetted perimeter in meters); S, the slope of channel (channel gradient); the constant *k* equals 1.486 if English units are used or 1 with metric units; and n, Manning's roughness coefficient. Stream-specific Aquatic Habitat Inventory data (see appendix Y) were used to estimate the stream channel cross-section shape and cross-section area. If the predominant depth was greater than half the bankfull width, the cross-section channel shape was assumed to be a V. If the bankfull depth was less than half the bankfull width, the cross-section channel shape was assumed to be a trapezoid with each bank as a 1:1 slope, dependent on predominant depth (bottom = W – (2 D)). If the bankfull depth was equal or greater than half the bankfull width, the cross-section channel shape was assumed to be a V. Manning's n was estimated from various sources (Chow 1959; Limerinos 1970; Arcement and Schneider 1989) and ranged from n = 0.060 for floodplain channels with light brush and trees in summer, to n = 0.050 for channels with pools, shoals and stones to n = 0.045 for mountain streams with bottom gravels, cobbles, and boulders and no vegetation in the channel (Chow 1959).

Estimates of Q derived with Manning's Formula are assumed to be measures of the carrying capacity (bankfull flow) of a particular channel section (Arcement and Schneider 1989). Carrying capacities of a channel section are assumed to occur during periods of high flow, generally during winter months in the Pipeline project area. Stream flow rate or discharge rate, Q, is related to cross-sectional area (A) and average streamflow velocity (V_A):

$$Q = A \cdot V_A, \text{ alternatively } V_A = Q / A$$

Estimates of Q derived with Manning's Formula are assumed to be measures of the carrying capacity (bankfull flow) of a particular channel section (Arcement and Schneider 1989). Carrying capacities of a channel section are assumed to occur during periods of high flow, generally during winter months in the Pipeline project area. Estimates of variables used to derive Q and V_A are provided in table 3.5.4-18, averaged by watershed.

TABLE 3.5.4-18

a/ Stream-specific estimates are provided in appendix Y.

Seasonal Discharge. Pipeline construction across waterbodies would occur during ODFW (2008) in-stream construction windows (section Timing to Life History Functions, above). Hydrographs of monthly discharges of waterbodies within the Coos (figure 3.5.4-4), Coquille (figure 3.5.4-5), and South Umpqua (figure 3.5.4-6) subbasins to be crossed by the Pipeline show peak seasonal flows during winter months, December through February. Lowest flows occur during summer months, coinciding with the ODFW construction windows. Assuming that high winter stream flows correspond to the bankfull carrying capacities of channel sections (Arcement and Schneider 1989), in-stream flows during the ODFW construction window would be some fraction of the winter flows. Those fractions are included in table 3.5.4-19 with the mid-point that is used to adjust low flows and velocities for each sampled reach of Aquatic Habitat Inventory data (see appendix Y).

TABLE 3.5.4-19

Recorded High Flows During Winter and Average Low Flows during the ODFW In-stream Construction Window in Hydrographic Data within the Coos, Coquile, and South Umpqua Subbasins Crossed by the Pipeline Project

S. Umpqua River	6,862 (Dec)	Jul 1-Aug 31	196	2.9	

a/ Ten-year flows in Pony Creek were evaluated from 1992 to 2001 rather than from the most recent 10-years, 1999 to 2008, because of releases from Upper Pony Creek Reservoir since completion of the new dam in 2001.

The 10-year average of low water stream flows in the Coos Subbasin during the ODFW in-stream construction window are assumed to be 1.4 percent of high winter flows (see table 3.5.4-19) based on discharge data for Pony Creek and West Fork Millacoma River during December (see figure 3.5.4-4). Average low water flows in the Coquille Subbasin during the construction window are 2.0 percent of high winter flows (see figure 3.5.4-5) and average low flows in the South Umpqua Subbasin are 2.8 percent of high winter flows (see figure 3.5.4-6). Stream depths for all waterbodies within the each subbasin were reduced by the same proportion through iterations that reduced bankfull flows in the Coos, Coquille, and South Umpqua subbasins by 1.4 percent, 2.0 percent, or 2.8 percent, respectively, in all streams in the Aquatic Habitat Inventory samples. Reduced stream depths generate reduced values of A, P, and R in Manning's Formula. Stream-specific estimates of Q and V_A during low water flow conditions were likewise derived and are provided in table 3.5.4-20, averaged by watershed. Reduced stream depths generated reduced values of A, P, and R in Manning's Formula.

<u>Background Turbidity and Suspended Sediment</u>. Turbidity, generally reported in NTUs, is a measure of the lack of transparency (cloudiness) of water caused by suspended or dissolved substances that cause light to be scattered and adsorbed. Turbidity is often measured on-site using a turbidity meter that measures the scattering of light in a water sample relative to a known range turbidity standards. Turbidity is directly related to the concentration of sediments suspended in water but the relationship between turbidity and suspended sediment is complicated by sediment particle size, particle composition, and water color (ODEQ 2010).

GeoEngineers (2017f) evaluated the potential risk of turbidity increasing during construction across waterbodies. The qualitative evaluation was based on each affected waterbody's hydroperiod, presence of erodible clay and loam soils in streambanks, presence of clay in streambed (suspended clay contributes to turbidity disproportionally to its erodibility), long-term stability of stream channels, and level/duration of construction effort and stabilization measures likely added at the time of construction. The turbidity risk was scored from 1 (low) to 5 (high).

a/ Stream-specific values are provided in appendix Y.

Of 133 waterbodies evaluated within range of Oregon Coast coho, 23 were scored with a low risk (score of 1 or 2) of turbidity increase over a 24-hour period, and 110 were scored with a moderate risk (score of 3 or 4), generally due to soil erosion potential, presence of clay or mud, and/or the presence of steep slope or an incised channel that would require construction of a deep trench (GeoEngineers 2017f). The evaluation concluded that turbidity generated during construction may exceed Oregon water quality standards for short distances and short durations downstream from each stream crossing, either coinciding with construction across perennial waterbodies or in intermittent streams coincidental with autumn precipitation.

Ambient turbidity was not addressed by GeoEngineers (2017f). Turbidity (NTU) has been evaluated by ODEQ (2013) and retrieved from Laboratory Analytical Storage and Retrieval (LASAR) Web Application in 2013 before ODEQ discontinued support of the site (ODEQ 2017), making the data unavailable. Turbidity within individual streams may be highly variable, but during the period coinciding with ODFW (2008) in-stream construction windows, reported turbidity was minimal and of low variability in streams for which data exists (see table 3.5.4-21).

The majority of ODEQ LASAR data were turbidity (NTU) measurements taken in the field. TSS were occasionally been reported but mostly without measuring corresponding turbidity. Relationships between turbidity and suspended solid concentrations are best if determined on a stream-by-stream basis (Downing 2008). However, since stream-specific data for turbidity and TSS were not available, four available literature generated models were used to supply a reasonable range of the possible relationships. Relationships are reported for streams in Alaska (Lloyd 1987; Lloyd et al. 1987) and streams in the Puget Lowlands (Packman et al. 1999); the models are non-linear. At low turbidity levels (see table 3.5.4-21), conversions of NTUs to TSS are relatively consistent among the models. Based on these conversions, an overall background level of 2 mg/l is assumed for TSS concentrations for all streams crossed by the Pipeline during the ODFW in-stream construction window. Available turbidity data (NTU) from stations included in the table averaged for July, August, and September yielded an average of 0.8 NTU. When converted to TSS using the models in the table, the conversion yields an average of 1.0 mg/l as a background level within range of the Oregon Coast coho. In support of that assumption, ODEQ (2010) reported that during dry seasons, background turbidity levels are relatively low and consistent in small streams throughout Oregon, generally from 1 to 2 NTUs. A background TSS concentration of 2 mg/l during summer is also consistent with measurements reported by USGS in Myrtle Creek, Big Butte Creek, and the Rogue River mainstem during summers 1977, 1978, and 1979 (historical data provided by the Forest Service. Results from the ODEQ data analysis and other sources reported above support using 2 mg/l as ambient TSS levels during the in-stream crossing period including all or portions of July, August, and September.

				Model 1 Mean TSS (Maximum) (Minimum)	Model 2 Mean TSS (Maximum) (Minimum)	Model 3 Mean TSS (Maximum) (Minimum)	Model 4 Mean TSS (Maximum) (Minimum)

a/ Models used to convert Turbidity (T) to Suspended Solids Concentration (SSC) or Total Suspended Solids (TSS) in waterbodies crossed or proximate to the Pipeline project . Turbidity information source: ODEQ (2013) included data collected prior to 2013.
Model 1 (Lloyd 1987; Lloyd et al. 1987) applicable to waters throughout Alaska: $T = 0.44 (SSC)^{0.858}$
Model 2 (Lloyd 1987; Lloyd et al. 1987) applicable to interior Alaskan streams: $T = 1.103 (SSC)^{0.968}$
Model 3 (Packman et al. 1999) Rutherford Creek, King County, Washington: $\ln(TSS) = 1.32 \ln(NTU) – 0.68$
Model 4 (Packman et al. 1999) nine streams sampled in the Puget Lowlands, Washington: $\ln(TSS) = 1.32 \ln(NTU) + 0.15$

NTU – nephelometric turbidity unit

Particle Transport. Sediment particles will be transported distances downstream (L, in meters) based on 1) the particle size and settling velocity (V_S, - centimeters per second – in water at 20°C, see for example the Wentworth Grain Size Chart, USGS 2003), 2) the average streamflow velocity (meters per second), and 3) the average depth of flow (D, meters) downstream, using the following "velocity-distance-time" equation;

$$L = V_A (D / V_S)$$

Estimates of transport distances (L in meters) for various sediment particles ranging in sizes from clay to coarse gravel are provided, as examples, in table 3.5.4-22 for three waterbodies in the Pipeline project vicinity for which data are available. Particle sizes deleterious to salmonids (250 µm or less in the models of Newcombe and Jensen (1996), above) could settle out of suspension less than 1 meter (0.2 feet) downstream (e.g., medium sand in low flows for Tributary to Catching Creek). Alternatively, particles could remain suspended for 4.7 kilometers (2.9 miles) or more (very fine silt in Willis Creek).

TABLE 3.5.4-22

Estimated Downstream Transport Distances for Particles
(ranging from Very Fine Silt to Coarse Gravel) in Three Streams (as examples).

Particle Description	Particle Diameter a/	Settling Velocity (V_S)	Estimated Particle Transport Distance (L) Downstream b/		
			Tributary to Catching Creek	Steele Creek	Willis Creek
Coarse Gravel	1.60 cm	90 cm/s	0 m	0 m	0 m
Very Coarse Sand	0.1 cm	15 cm/s	0 m	0 m	0 m
Coarse Sand	0.05 cm	8 cm/s	0 m	0 m	1 m
Medium Sand	0.025 cm	3 cm/s	0 m	0 m	2 m
Fine Sand	0.0125 cm	1.25 cm/s	0 m	1 m	5 m
Very Fine Sand	0.0062 cm	0.329 cm/s	1 m	4 m	20 m
Coarse Silt	0.0031 cm	0.085 cm/s	3 m	16 m	78 m
Medium Silt	0.0016 cm	0.023 cm/s	9 m	59 m	289 m
Very Fine Silt-Clay	0.0004 cm	0.0014 cm/s	153 m	977 m	4,742 m

a/ note that 0.025 cm = 250 µm

b/ Parameter values used to estimate L:

Trib. Catching Creek: V_A =0.27 m/s; D = 0.01 m.
Steele Creek: V_A = 0.53 m/s; D = 0.03 m.
Willis Creek: V_A = 0.66 m/s; D = 0.1 m.

Sediment Generated During Pipeline Construction. Modeled concentrations of TSS produced in waterbodies during wet open-cut pipeline construction were developed from empirical data collected during construction across 15 to 19 streams in North America (Reid et al. 2004). Models were developed to predict mean TSS concentrations immediately downstream (approximately 50 meters) of pipeline construction sites. Models included TSS generated by all construction activities and by trenching, pipe lowering, and backfilling. The models predicting mean TSS generated by all activities (including trenching, pipe lowering, and backfilling) had the highest correlation coefficients (Reid et al. 2004). The model predicting mean TSS (***C*av**) at about 50 meters downstream by all activities associated with wet open-cut pipeline construction is:

$$C_{av} = 1.5 \times 10^6\ U^{1.09}\ d_{50}^{0.95}\ P_f^{0.35}\ q^{-1}$$

where *U* = mean flow velocity (m per second) at the crossing location during the construction period, equivalent to V_A derived using Manning's Formula (table 3.5.4-17 and appendix Y); d_{50} = the median sediment size (m) of the excavated material by weight, P_f = percentage of fines (silt and clay) in the excavated material (%) and is assumed to equal the percent of silt and organics in surface substrates for all streams within a given fifth-field watershed (estimated as 2/3 of the Percent Sand, Silt, Organics in Substrate tabulated in table 3.5.3-12); *q* = the width adjusted stream flow rate where *q* = *Q/B*, (m^2 per second) with *B* = the watercourse width (m) adjusted for a particular flow rate and *Q* = stream flow rate (m^3 per second) derived using Manning's Formula (values for *Q* are in table 3.5.4-18 and appendix Y). Values for d_{50} in these analyses were derived by regressing values of d_{50} and P_f provided in Table 2 of Reid et al. (2004); the relationship of d_{50} to P_f from that study is $d_{50} = 38.12\ e^{-0.0963\ Pf}$ (r^2 = 0.636, P<0.001).

In these simulations, Q is related to B through Manning's Formula and as B increases numerically, Q also increases but at a faster numerical rate (as a power function). If all other model parameters are held constant in the Reid et al. (2004) model, increased width adjusted stream flow rate, *q* (due high flow, Q, and proportionally smaller watercourse widths, *B*) will decrease the TSS concentration (C_{av}) because *q* is factored as q^{-1} in the equation. Conversely, lower *q* values will generate higher C_{av} with all other parameters in the equation held constant. Stream-specific estimates of *U, d50, P_f*, q^{-1}, and C_{av} during low water flow conditions are provided in appendix Y and averaged by watershed in table 3.5.4-23.

In addition to developing predictive models of TSS concentrations generated by wet-open cut pipeline construction, Reid et al. (2004) measured TSS downstream from 12 flumed pipeline crossings and 23 dam-and-pump crossings (dry-open cut or isolated pipeline construction crossings) with comparisons to 11 wet open-cut construction crossings. By accounting for flow, background TSS concentrations, sampling distance downstream, and duration of construction, Reid et al. (2004) determined that mean TSS concentrations generated during dry open-cut construction by fluming were 3.7% of the wet open-cut concentrations and were 0.85% of the wet open-cut concentrations for dam-and-pump construction. These relationships were used in table 3.5.4-24 to adjust average TSS concentrations estimated at 50 meters downstream from wet open-cut pipeline crossings to average TSS concentrations at flumed pipeline crossings and dam-and-pump pipeline crossings.

Estimated Downstream Distance of Suspended Sediment. Ritter (1984) provided a variant of the "velocity-distance-time" equation, above to estimate concentrations of suspended sediments (C_X, as mg/L) some distance (x) downstream from a pipeline trench being constructed across a waterbody. Ritter's model for downstream sediment transport distance during construction across minor streams, with complete mixing of sediment particles, estimates the concentration downstream C_X by:

$$C_X = C_O e^{-(vs/d)(x/u)}$$

where C_O (mg/L) is the initial concentration of suspended solids in the water column at the trenching site, vs = the settling velocity (m/second) of sediment particles, d = stream depth (m), u = stream current velocity (m/second), and x = distance (m) downstream.

The formula for estimating the concentration downstream (Ritter 1984) is used to estimate the distance downstream for TSS concentrations at 50 m (C_O) to equal assumed ambient concentrations (C_X = 2 mg/l). The estimate is calculated by solving for x (distance) in the equation with appropriate transformations and inclusion of only the estimated clay fraction as TSS concentration since the silt fraction would settled out of suspension upstream:

$$x = (\ln(C_X) - \ln(C_O)) + (d / vs)\, u$$

where x = distance (m) downstream, C_O = the initial concentration (mg/l) of suspended solids in the water column at the trenching site, vs = the settling velocity (m/second) of the clay fraction, d = stream depth (m), u = stream current velocity (m/second), and x = distance (m) downstream. The distances x for TSS generated by wet open-cut construction techniques to attenuate to ambient TSS (C_X) is provided in table 3.5.4-24.

Inverse relationships between TSS concentrations produced at 50 meters from in-stream construction and TSS concentrations at variable distances downstream were evaluated for each of the three pipeline crossing techniques by nonlinear regressions of distance downstream (from 1 to 1000 m) and total TSS concentrations at distance x, solving for x in the above equation [$x = (\ln(C_X) - \ln(C_O)) + (d / vs)\, u$]. Best fit regression models were selected (exponential vs. logarithmic) to model the inverse relationships between distance and TSS concentration for data averaged in each watershed. Those regression equations are provided in table 3.5.4-25 and define the nonlinear relationships between y = concentration (mg/l) and x = downstream distance (m).

Suspended Sediment Downstream Effects. Newcombe and Jensen (1996) developed six different models assessing effects of TSS on various fish and habitat groupings. As noted above the model addressing effects on both adult and juvenile stages of salmonids (Model 1) provides the best overall assessment of general level of severity of effects for juvenile and adult coho salmon in project area streams at the time of instream construction. Input for the model includes TSS concentration (mg/l) and duration (hours) of exposure to the suspended sediments and has the form:

$$z = a + b\,(\log_e x) + c\,(\log_e y)$$

where z = SEV score, x = duration of exposure in hours, and y = concentration of suspended sediment in mg/l. Constants a, b, and c were empirically derived for Model 1, used here, and other models (see Table 3, in Newcombe and Jensen 1996). If duration of exposure is known, and z (SEV) is set as a defined value, TSS concentration for that defined SEV score can be computed as:

$$y = e^{((z - a) - b\,(\log e\ x))\,/\,c} \text{ or } y = \exp\,(((z - a) - (b\,(\log_e x)))\,/\,c$$

In any of the Newcombe and Jensen models, there is a nearly consistent range for the whole number z, varying from z – 0.5 to z + 0.49. For example, if SEV = 3, the range for that score in the exponential equation, above would be between 2.50 and 3.49; for SEV = 5, the range is 4.50 to 5.49, and so on. For any given duration of exposure (x), the TSS concentration (y) is minimized using (z – 0.5) in the solution. Using the minimum TSS concentration for any given SEV score maximizes the predicted downstream distances for that concentration when solving the regression equations in table 3.5.4-25 for each of the three waterbody crossing methods in each of the nine watersheds.

contractor EnSite USA were asked to provide typical durations, based on their experience, for in-stream time requirements for placing and removing isolation structures for streams in different width categories. High pulses of sediment suspended during dry open-cut procedures are generated during installation and removal of isolation structures prior to and after fluming or dam-and-pump installation, trenching, pipe installation, and trench backfilling. EnSite provided the following durations of typical sediment pulses for four stream width classes during installation of stream-crossing structures: for widths ≤10 feet - 2 hours; widths >10 feet to ≤25 feet - 4 hours; >25 feet to ≤50 feet - 5 hours; and > 50 feet to ≤100 feet, 6 hours. EnSite also provided the following durations of sediment pulses for the same four width classes during removal of dry open-cut crossing structures: for widths ≤10 feet - 2 hours; widths >10 feet to ≤25 feet - 3 hours; >25 feet to ≤50 feet - 4 hours; and > 50 feet to ≤100 feet, 5 hours. Numbers of streams in range of Oregon Coast coho and streams with coho and streams with assumed coho presence within those four width categories that would be crossed by the Pipeline in each watershed are provided in table 3.5.4-26 using the worst case of structure installation. In general, there are very few streams with widths >25 feet.

TABLE 3.5.4-26

Numbers of Streams in Range of Oregon Coast Coho within Four Width Classes that Would Be Crossed by Dry Open-Cuts and Estimated Durations (Worst Case) for In-stream Sediment Generating Actions

Subbasin and Fifth-Field Watersheds	Total Number of Streams Crossed	Total Streams Crossed with Coho a/	Number by Width Class and Duration b/			
			≤10 ft 2 hours	>10 to ≤25ft 4 hours	>25 to ≤50 ft 5 hours	>50 ft 6 hours

a/ Includes assumed presence from table 3.5.4-4 but not coho in the Coos Bay Estuary
b/ Durations for structure installation by width class provided by personnel with pipeline contractor EnSite USA

SEV Scores Downstream. Durations for in-stream sediment generating actions provided by EnSite USA from table 3.5.4-26 are used in table 3.5.4-27 with minimun TSS concentrations for specific SEV scores ranging from minor behavioral effects (SEV = 1, alarm reaction) to extreme sublethal effects (SEV = 8, major physiological stress) to estimate the maximum downstream distances at which those severity of ill effects would occur to Oregon Coast coho by in-stream construction across streams in the four watersheds.

Failures of isolation structures to exclude streamflow during fluming or dam-and-pump would result in suspended sediment entrained downstream, assumed to be equal to TSS levels generated during wet open-cut in table 3.5.4-27. Scenarios of exposures as long as six hours could occur while work crews repair the failed isolation structures. Six-hour exposure would cause SEV = 7 (moderate habitat degradation, impaired homing) for all stream widths and could cause major physiological stress (SEV = 8) to Oregon Coast coho for relatively short distances downstream (<55 meters) in six of the nine watersheds in table 3.5.4-27. Longer exposures could be required if dry open-cut construction (flume or dam- and-pump) is abandoned and the waterbody crossing is completed using wet open-cut construction.

Values of 0, in columns associated with specific SEV scores and TSS concentrations in table 3.5.4-27, indicate that there are no distances downstream from construction by wet open-cut or dry open-cut (flume or damp-and-pump) that the specified TSS concentration and exposure duration during a particular crossing method would generate the SEV score for that column in that watershed. For example, there is no distance downstream for construction during fluming in the Days Creek-South Umpqua River watershed at which a SEV score = 5 if the TSS value of 59.4 mg/l and the exposure duration is 2 hours.

The modeling results provided in table 3.5.4-27 provide the maximum downstream distances that TSS generated by each of the crossing methods would attenuate to the concentrations shown (rows labeled TSS (mg/L) with specific durations based on stream width (groupings labeled with width category followed by hours) that would yield a specific SEV score (columns SEV=1 to SEV=8) for fluming or dam-and-pump crossing methods. Using estimates for fluming in streams ≤10 feet wide within Coos Bay Frontal-Pacific Ocean watershed as an example, for the range of distance = 0 (actually 50 meters downstream from the pipe trench as applied in the Reid et al. 2004 model for average TSS generated by all activities) to distance = 24 m, SEV =5 with TSS concentration = 59.4 mg/l and duration = 2 hours. Other estimates include:

- From downstream distance = 24 m to distance = 478 m, SEV = 4 with TSS concentration = 15.3 mg/l and duration = 2 hours.
- From downstream distance = 478 m to distance = 1,031 m, SEV = 3 with TSS concentration = 3.95 mg/l and duration = 2 hours
- From downstream distance = 1,031 m to distance = 1,257 m, SEV = 2 with TSS concentration = 1.02 mg/l and duration = 2 hours.
- From downstream distance = 1,257 m to distance = 1,323 m, SEV = 1 with TSS concentration = 0.26 mg/l and duration = 2 hours.
- Past distance = 1,323 m downstream, SEV = 0.

a/ Durations for wet open-cut indicate time to repair isolation structures after failure. Durations for dry open-cut from table 3.5.4-26.

b/ Maximum downstream distances derived by solving SEV equation ($Y = e^{((z - a) - b (\log_e x)) / c}$) for concentration (Y) by minimizing SEV scores (Z -0.5) and using durations (hours) from table 3.5.4-26. Concentrations derived from appropriate equations, table 3.5.4-25.

Evident from examining table 3.5.4-27, no flumed crossings in any of the four watersheds would cause SEV scores greater than 5 (sublethal effects including minor physiological; increase in rate of coughing; increased respiration rate) except for distances 2 meters or less downstream when fluming waterbodies >25 feet wide in the Coos Bay Frontal-Pacific Ocean and Myrtle Creek watersheds. Likewise, no crossings with dam-and-pump procedures applied would cause SEV scores greater than 4 (sublethal effects, including short-term reduction in feeding rates; short-term reduction in feeding success) except for distances of 1 meter downstream when fluming waterbodies >50 feet wide in the Coos Bay Frontal-Pacific Ocean and Myrtle Creek watersheds. Except for possible failures of isolation structures that would cause TSS concentrations similar to wet open-cut procedures with exposures as long as 6 hours (discussed above), no in-stream construction would cause moderate or major physiological stress (SEV scores 6 to 8, respectively; see Newcombe and Jensen 1996) or cause lethal conditions for salmon (SEV > 8).

A failure of crossing isolation structures lasting up to 6 hours could cause a SEV score of 8 (major physiological stress; long-term reduction in feeding rate/feeding success; poor condition) up to 40 meters downstream and a SEV score of 7 (moderate habitat degradation, impact on homing) for at least 542 meters downstream from dry open cut crossings within five streams with critical habitat in the Coos Bay Frontal-Pacific Ocean watershed; SEV score of 8 up to 23 meters and SEV score of 7 up to 1,185 meters of three streams crossed by dry open-cut with critical habitat within the North Fork Coquille River watershed; SEV score of 8 up to 26 meters and SEV score of 7 up to 1,999 meters of two streams crossed by dry open-cut with critical habitat within the East Fork Coquille River watershed; SEV score of 8 up to 10 meters and SEV score of 7 up to 1,534 meters of two streams crossed by dry open-cut with critical habitat within the Olalla Creek-Lookingglass Creek watershed; SEV score of 7 up to 856 meters of four streams crossed by dry open-cut with critical habitat within the Clark Branch-South Umpqua River watershed; SEV score of 8 up to 54 meters and SEV score of 7 up to 1,544 meters of three streams crossed by dry open-cut with critical habitat within the Myrtle Creek watershed; and SEV score of 7 up to 16 meters of four streams crossed by dry open-cut with critical habitat within the Days Creek-South Umpqua River watershed. To ensure a SEV score less than 7 (moderate habitat degradation, impact on homing), in-stream work to repair a failed containment structure would likely have to be restricted to less than 4 hours.

Similar analyses were conducted for individual streams to be crossed in each watershed that provide critical habitat and fresh water EFH for Oregon Coast coho salmon. Based on the width-specific durations of exposure (table 3.5.4-26) and the minimum TSS concentrations and concomitant miximum distances downstream produced by fluming or dam-and-pump construction methods to equate to specific SEV scores (table 3.5.4-27), the greatest risk to Oregon Coast coho would be 1 to 2 meters downstream during fluming in streams greater than 25 feet wide within the Coos Bay Frontal and Myrtle Creek watersheds (table 3.5.4-27). At those distances, SEV = 6 causing moderate physiological stress for juvenile or adult coho.

The possibility for known or assumed salmon-bearing streams to be affected by TSS generated during dry open-cutting neighboring streams was explored at the request of NMFS (NMFS 2017i). Distances of nearest neighboring streams from each salmon-bearing stream are included in table 3.5.4-28. Nearest-neighbor streams are only considered for effects if they are within the same fifth field watershed as the targeted stream. Distance for the confluence of a nearest neighbor stream with a coho-bearing stream is assumed to be the same as the distance between the two stream crossing sites, forming an equilateral triangle. For each neighboring stream, maximum downstream distances for minimum TSS concentrations that produced the highest SEV score were computed with the same procedure described and available in table 3.5.4-27. If a stream had bedrock substrate, dam-and-pump crossing was assumed, otherwise a flumed crossing was assumed.

None												

a/ Risks from downstream TSS by crossing all streams with bedrock substrate are considered None to Low; risks of downstream TSS crossing intermittent streams are considered None to Low; risks from downstream TSS by crossing perennial streams are considered Moderate to High.
b/ Highest SEV scores for each given crossing method and stream width category in specific watershed provided in table 3.5.4-27
c/ Distance for confluence of nearest neighbor with coho stream is assumed to be the same as the distance between the two stream crossing sites, forming an equilateral triangle.

If the nearest neighbor distance to a salmon-bearing stream exceeded the maximum distance with highest SEV score downstream from the neighbor stream, then "None-Low" risk of TSS to the salmon-bearing stream produced during construction of the neighboring stream is assumed. Construction across nearest neighbors could generate some level of risk for elevated TSS concentrations in the known or assumed salmon-bearing streams crossed in the range of Oregon Coast coho. In table 3.5.4-28, risks from downstream TSS by crossing any stream with a bedrock substrate are considered "None-Low" because fine sediment (silt and clay) would not be mobilized in the water column; risks of downstream TSS crossing intermittent streams are considered "None-Low" because those streams would likely be dry during the in-stream construction period (ODFW 2008); risks from downstream TSS by crossing perennial streams are considered "Moderate-High" because flowing water would be present at the time of construction. The highest risk for SEV = 5 (causing minor physiological stress) would occur at the confluence of the nearest neighbor to Rock Creek (Myrtle Creek watershed). All other SEV values at a nearest neighbor's confluence to coho-occupied and streams with critical habitat are SEV ≤ 4. However, the estimated TSS concentration at any nearest neighbor tributary confluence would be diluted by greater flow rates and water volumes in larger streams occupied by coho and therefore the estimated SEV in the coho stream would be considerably less than at the confluence.

A similar analysis of sediment effects on EFH streams known to support Oregon Coast coho that are not directly crossed by the Pipeline but have a tributary that would be crossed and which could have an effect on the EFH fish-bearing stream is provided in Section 4.2.3.2. However, conducting the analysis required a different methodology than used in the nearest neighbor analysis provided for Oregon Coast coho, above.

Downstream effects and maximum SEV levels that could occur during diverted open-cut to cross the South Umpqua River at MP 94.73 are unknown. As discussed below, sediment generated by diverted open cut of the South Umpqua River would not severely impact juvenile or adult salmonids or salmon eggs or larvae downstream due, in part, to the short downstream transport distance of very coarse pebbles, but also because the grain size would not be within the range of particulates that cause adverse effects to fish under any duration of exposure. There would be short-term turbidity increases for short distances lasting for several hours during portions of the installation and removal of the diversion structures for the proposed diverted open-cut crossing of the South Umpqua River. However, suspended sediment generated during construction at this crossing would likely be less than levels that cause minor physiological stress for fish (SEV=5).

Suspended Sediment – HDD

The Coos River at MP 11.13 is the only site within the riverine analysis area proposed to be crossed using HDD. At that location, Coos River is tidally influenced and the analysis of suspended sediment associated with HDD was discussed above with effects to HDD across the Coos Bay Estuary, estuarine analysis area.

Suspended Sediment – DP Crossing

DP technology would be used to cross the South Umpqua River at MP 71.3. Like HDD, DP crossings use a bentonite lubricant that theoretically could have an inadvertent return to the surface where it could enter the water contributing to suspended sediment levels. DPs are completed using an articulated, steerable MTBM mounted on the leading end of the product pipe or casing which is jacked into position using a pipe thrusting machine mounted at or near the ground surface. Soil and rock are excavated by the cutting head and removed through pressurized slurry pipes to the launching pit at a rate that is balanced with the advance rate of the machine, as the MTBM and pipe are jacked through the formation. A pipe-thrusting machine located in or near the launching pit provides the necessary force to advance the product pipe and provide the face pressure required for excavation. Small sections of pipe are welded to the back of subsequent sections after each section is advanced. Friction between the pipe and surrounding soil can create significant resistance during DP installation. To reduce the frictional resistance, over cutting is employed to create a small annular space between the pipe and external soil. The over cut is typically on the order of one to two inches.

The use of bentonite slurry helps reduce the frictional resistance between the pipe and soil as well as reducing the risk of collapse of the annulus around the pipe. Bentonite lubrication is typically added from the launch seal and from a specialized lubrication ring located behind the MTBM and in front of the jacking pipe. According to GeoEngineers' Technology Overview for Direct Pipe (see appendix E), the bentonite lubrication system used to lubricate the annulus between the product pipe and the excavation is introduced at a relatively low pressure reducing the potential for hydraulic fracture and inadvertent drilling fluid returns. Because the excavated hole is continuously supported and the risk of hydraulic fracture is low, the Direct Pipe alignment can be designed much shallower than is typical for HDD. Because of the limited amount of lubricant used and relatively low pressure of this construction, the chance of any inadvertent return occurring is remote. Therefore, the chance of accidental contribution of increased suspended sediment to this crossing is unlikely and adverse effects to Oregon Coast coho salmon in this area would be unsubstantial.

Suspended Sediment – Diverted Open Cut

The diverted open-cut crossing method would require an in-stream tie-in, but it would be made in the dry behind the diversion structure. During the crossing, initial trenching would first occur on the dry side of the river; however, depending on the water levels during the season, it may be necessary to install a diversion to push or divert the flow to at least the middle of the river. PCGP is proposing a diverted open-cut at the eastern crossing of the South Umpqua River at MP 94.7 because the river is too wide to utilize other dry crossing methods (flume or dam-and-pump).

The South Umpqua River channel is sufficiently flat, wide, and shallow to divert all of the river flow to one side or bank of the river while work is proceeding in the dry on the opposite bank. The eastern crossing of the South Umpqua River would require TEWAs to be located in the river and would require equipment to work in the river to place the diversion structures or dams to divert the river flow from one side of the river and then to the other. The diversion could be constructed using portadams, aqua dams, steel plates, plastic sheeting, and/or sand bags to divert the river's flow temporarily away from the work area in order to minimize contact between streamflow and the excavation and backfill activities. This would require PCGP to place equipment within the stream to install, maintain, and ultimately remove the diversion structures. PCGP estimates the crossing would take a minimum of 14 days to complete, including three to four days of in-stream work to install, rearrange, and remove the diversion structures.

Once the construction right-of-way has been isolated by the diversions and/or sediment control devices, trenching would proceed to approximately the middle of the river. Trench spoil would be stored within the stream channel below the diversion or sediment control structures to ensure that sedimentation from saturated materials does not flow back into the river. After the trench has been completed, a section of pipe would be placed in the trench. Trench boxes or another marker form would be placed at the end of the pipe section in the middle of the riverbed for the tie-in. The trench would be backfilled and the streambed restored to the original contour configuration, except for the immediate area around the tie-in.

The diversion structure would then be removed and rearranged to divert the flow temporarily to the other side or dry side of the river in order to minimize contact between streamflow and the excavation and backfill activities. This would again require PCGP to place equipment within the stream to rearrange the diversion structures. Once the diversion structures have been properly reconfigured and extended beyond the tie-in location and the river flow diverted to the opposite side of the river, excavation for the other section of pipe would begin. Trenching would proceed across the river bed to the tie-in point in the middle of the river where it would be uncovered. Once the excavation is complete, the second pipe section would be carried in and tied into the first section. After the tie-in has been made, the streambed would be restored to its original contours and configuration and the diversions structures would be removed. Streambanks would be re-established and stabilized.

During the diverted open-cut at the eastern crossing of the South Umpqua River, multiple discharge pumps would be required to keep the tie-in area dry while the welds are being made and to control any flow seepage in the work areas. The discharge from this activity would occur to a straw bale discharge structure located in an upland area as far away from the river as possible to prevent any silt-laden water from flowing into the river.

GeoEngineers (see appendix E.2 to PCGP's Resource Report 2) provided results of sampled grain-size diameters of pebbles counted at the proposed diverted open-cut crossing site in the South Umpqua River (see table 1 in appendix E.2). The smallest grain reported is 1.6 inches diameter which is classified as a "coarse" to "very coarse pebble" (see Wentworth Grain Size Chart, USGS 2003) with an approximate settling velocity (in water at 20°C) of about 73 cm/sec or 0.24 feet/second. GeoEngineers also estimated discharge (cfs) in the South Umpqua River during the construction period (see table 2 in appendix E.2) and estimated maximum water depths and velocities under diverted flow conditions (see table 3 in appendix E.2). Those estimates ranged from a 4.9 feet depth with water velocity of 1.9 feet/second at discharge of 110 cfs to a 6.3 feet depth with velocity of 4.7 feet/second during discharge rate of 340 cfs. Based on the grain settling velocity (V_S), the stream flow velocity (V_A), and stream depth (D), the downstream distance (L) of grain transport is estimated by

$$L = (D \cdot V_A) / V_S$$

The composition of stream bed subsurface in the South Umpqua River channel was not sampled. However, GeoEngineers (2015) previously completed four geotechnical borings in the vicinity of the proposed crossing for the purpose of evaluating HDD feasibility. The boring logs are included in Appendix B within GeoEngineers' report. The borings were completed within the floodplain adjacent to the channel upstream of the proposed crossing location. Extrapolation of the information suggests bedrock is present at shallow depths throughout the streambed and adjacent floodplain. The depth to bedrock varied between approximately 3 feet at boring B-3 to 21.5 feet at boring B-2. Boring B-2 also included sandy gravel with cobbles between the surface and the bedrock. The pebble count conducted near the proposed crossing yielded a grain-size distribution of the existing alluvial material (GeoEngineers 2015), which is consistent with the reported grain-size distribution with the materials identified in boring B-2.

For the smallest grain sampled in the substrate - very coarse pebble - the transport distance downstream from the diverted open-cut would range from 39 feet with 110 cfs to 123 feet with 340 cfs. The sediment generated by diverted open cut of the South Umpqua River would not severely impact juvenile or adult salmonids or salmon eggs or larvae downstream due, in part, to the short downstream transport distance of very coarse pebbles, but also because the grain size would not be within the range of particulates that cause adverse effects to fish under any duration of exposure (see Newcombe and Jensen 1996). Suspended sediment generated during construction at this crossing would likely be less than levels that cause physiological stress for fish (and may exceed the Oregon water quality standard for short distances and short durations downstream, either coinciding with construction across this perennial waterbody or coincidental with autumn precipitation. There would be short-term turbidity increases for short distances lasting for several hours during portions of the installation and removal of the diversion structures for the proposed diverted open-cut crossing of the South Umpqua River.

Movement Blockage

Of the 48 waterbodies with confirmed or assumed presence of Oregon Coast coho salmon, all but five will be crossed by dry open-cut. Dry open-cut construction is expected to block upstream movement by adult salmonids, as well as within stream movements of juvenile coho. Restrictions on migration could occur from short-term elevation of sediment and method of water diversion around the stream crossing area. As discussed above, fish are expected to abandon cover and/or avoid turbidity plumes generated by in-stream construction. In-stream construction would be completed prior to most upstream migrations by Oregon Coast coho.

In addition, block nets would be employed at all waterbody crossings in which water is present at the time of construction. Procedures to exclude fish from the construction right-of-way, maneuvering fish downstream of the crossing site, isolating and dewatering the construction site, removing fish from within the isolated construction site during dewatering, fish handling, holding and release, and monitoring with documentation are described in appendix T, *Fish Salvage Plan*. The *Fish Salvage Plan* was reviewed by BLM, Forest Service, and Bureau of Reclamation and each agency submitted documentation to PCGP stating that the plan was complete.

Flumes would maintain streamflow and fish might move upstream or downstream through the flume. With the dam and pump method, coho salmon would not be able to move upstream or downstream through the work area until the dams have been removed. Flumes and isolation structures (e.g., dams) would be removed as soon as possible following backfilling of the trench. Overall, the presence of temporary physical structures would not cause meaningful delays to adult upstream migrating coho salmon resulting in unsubstantial effects to coho salmon individuals.

The diverted open-cut of the South Umpqua River could take about 14 days to complete. Because one channel would be open during the entire crossing, no passage of fish would be impeded and no fish removal would be required. Overall, the levels of suspended sediment and physical structures would not cause meaningful delays to adult upstream migrating coho salmon resulting in unsubstantial effects to coho salmon individuals.

Newcombe and Jensen's (1996) Severity of ill Effect (SEV) scale includes avoidance behavior (SEV = 3), a behavioral effect that changes the activity patterns or alters the kinds of activity usually associated with an undisturbed environment (Muck 2010) and may indicate juvenile and/or adult coho instream movements would be affected. Likewise, an SEV score of 3 indicates a "measured change in habitat preference" in models developed by Anderson et al. 1996. SEV scores of 3 and higher due to elevated TSS concentrations are assumed to block or interfere with fish movements during durations of exposure to the suspended sediment downstream (provided in table 3.5.4-26). Downstream distances at which SEV ≥ 3 during fluming or dam-and-pump construction in each 5^{th} field watershed were provided in table 3.5.4-27.

Entrapment

Waterbody crossings using the "dry" crossing methods, flume or dam-and-pump, may result in some fish being entrapped in streams. Flumes and dams would be completely installed and functioning before any in-stream trenching disturbance occurs. Construction across a waterbody would take up to four days using dry open cut methods, but less for small and intermediate streams.

For a typical crossing, once streamflow is diverted through the flume pipe but before pipeline trenching begins, fish trapped in any water remaining in the work area between the dams would be removed and released using the *Fish Salvage Plan* (see appendix T). Salvage methods could include, seines, and/or dip nets and electrofishing (see section 3.5.4.4, Conservation Measures). Seining would be the primary method used to salvage fish but electrofishing methods may be used if all fish cannot be removed from the area potentially dewatered (see appendix T). All methods of capture and holding have risks of stress, injury, or mortality of fish. Fish inadvertently left within the dammed-off construction zone could be killed by impingement on pump intakes used to dewater the construction zone or would likely die once all water was removed. To eliminate or greatly reduce these effects, PCGP would contract with either ODFW or a qualified consultant to capture the fish. Fish removal personnel will be approved by ODFW and NMFS for this listed species. Personnel who would handle and/or remove fish on federal lands would be approved by the Forest Service or the BLM or be done directly by agency personnel if approved by ODFW. Overall, some listed juvenile fry coho salmon are likely to suffer injury or mortality but, with the implementation of project conservation measures, the numbers would be slight.

There are 89 waterbodies that would be crossed by flumed dry open-cut procedures, with an additional 22 waterbodies with bedrock streambeds that may necessitate blasting and/or use of mounted impact hammers (discussed above under Acoustic Shock) and require crossing with dam-and-pump construction. However, only eight of the streams with bedrock streambeds are known to support Oregon Coast coho and three others are assumed to be occupied by coho.

There are 43 streams (see table 3.5.4-2) known or assumed to support Oregon Coast coho that would be crossed by the Pipeline. There are thirteen known a streams that would be crossed in the Coos Bay Frontal-Pacific Ocean watershed; three known in the North Fork Coquille River; two known and six assumed streams in the East Fork Coquille River; no streams with coho presence (known or assumed) would be crossed in the Middle Fork Coquille River; two streams known to have coho and three assumed in the Olalla Creek-Lookingglass Creek watershed; four streams known (not including the South Umpqua River) with coho in the Clark Branch-South Umpqua River watershed; three known and two assumed coho streams crossed in the Myrtle Creek watershed; four known in the Days Creek-South Umpqua River; and (not counting the South Umpqua River). There are no streams, known or assumed to be occupied that would be crossed in the Upper Cow Creek watershed.

The width of the construction right-of-way across waterbodies would either be 75 or 95 feet. Fish would be salvaged from within the 75-foot or 95-foot wide right-of-way crossing of each dry open-cut stream where blasting is not expected. The fish salvage area would be isolated by sand bag dams installed upstream and downstream from the centerline.

Estimates of juvenile coho present in at crossing sites in streams were based on all rights-of-way are 95 feet wide at each stream crossing within which coho would be salvaged. Numbers of juvenile coho potentially present or assumed to be present in the streams with crossed by dry open-cut (no blasting) are provided in table 3.5.4-29 and do not include numbers within streams with bedrock substrates that were provided in table 3.5.4-16. In the 23 waterbodies known or assumed to be inhabited by Oregon Coast coho that would be crossed by fluming, 768 juvenile fry coho could be displaced and or salvaged prior to construction which does not include the 195 juvenile fry coho that could be salvaged from streams with bedrock prior to blasting (see table 3.5.4-16). The estimates in table 3.5.4-29 are based on no fish being herded out of the work area prior to dewatering (see *Fish Salvage Plan* in appendix T) so the actual number that would be salvaged is expected to be much less.

a/ Juvenile Fry Present at Each Crossing based on Juveniles per Mile (see table 3.5.4-7) within a stream crossing length of 95 feet (worst case, see text).
b/ Total Juvenile Fry Present (worst case) = number of Juvenile Fry Present at Each Crossing multiplied by number of Dry Open-Cut

TABLE 3.5.4-29

Worst Case Estimates of Juvenile Coho Present or Assumed as Present at Streams Crossed by Dry Open-Cut (Fluming only, No Blasting Assumed) and Juveniles Salvaged Prior to Construction of the Pipeline Project within the Oregon Coast ESU

Subbasin and Fifth-Field Watersheds	Dry Open-Cut w/ Juvenile Fry Coho Present, Assumed	Juvenile Fry Present at Each Crossing a/	Total Juvenile Fry Present b/	Juvenile Fry Salvaged at Each Crossing c/	Total Juvenile Fry Salvaged d/

crossings with with Juvenile Fry Coho Present or Assumed.
c/ Juvenile Fry Salvaged at Each Crossing based on Juveniles per Mile (table 3.5.4-7) within a stream crossing length of 95 feet (worst case, see text).
d/ Total Juvenile Fry Salvaged (worst case) = number of Juvenile Fry Salvaged at Each Crossing multiplied by number of Dry Open-Cut crossings with Juvenile Fry Coho Present. The estimate is based on no fish being herded out of the work area prior to dewatering (see *Fish Salvage Plan*). The actual number that would be salvaged is expected to be much less.

Riparian Vegetation Removal and Modification

Vegetated areas adjacent to waterbodies have been classified/defined in different ways depending on the resource and/or management objective being analyzed. Analyses conducted for Oregon Coast coho have considered effects to riparian vegetation present within a one site-potential tree height (1SPTH) buffer on either side of a waterbody on both federal and non-federal lands. This analysis area was determined in discussions with NMFS, USFWS, and other federal agencies during Interagency Task Force meetings.

Riparian Reserves are areas that are managed to protect habitat for fish species, as well as other riparian-dependent plants and animals on federal lands (BLM and Forest Service lands). Riparian Reserves include areas that range in size from 1SPTH to 2SPTH buffers on either side of a waterbody, depending on the waterbody type. Analyses to coho salmon here do not consider effects to Riparian Reserves because those effects would be limited to certain federal lands and analyses provided below consider effects on all lands, hence the analysis of effects to Riparian Zones rather than to Riparian Reserves. This analysis considered all intermittent and perennial waterbodies crossed and adjacent to the Pipeline in the range of Oregon Coast coho and also included waterbodies that are not assumed to have coho present.

Aquatic resources could be affected as a result of removal of vegetation and habitat at the waterbody crossing sites as required for construction. Short-term, physical habitat disruption would occur during trenching activities. Long-term degradation of habitats could occur if the stream contours are modified in the area of the crossing; the flow patterns are changed; and if erosion of the bed, banks, or adjacent upland areas introduces sediment into the waterbody. Loss of riparian vegetation along the banks would reduce shade, potentially increasing water temperatures, remove an important source of terrestrial food for aquatic organisms, and decrease LWD and the associated reduction in habitats, and potentially increase mass slope failures adjacent to waterbodies.

Much of the impact to coldwater anadromous and resident fisheries by past land uses have been alterations of riparian habitats by logging, road building, agriculture, or other developments such as residences and utility corridors. A total of 201.29 acres of vegetation within riparian zones one site-potential tree height wide (ranging from 164 feet wide for Days Creek-South Umpqua River watershed to 225 feet wide in Coos Bay Frontal-Pacific Ocean watershed) associated with waterbodies within range of the Oregon Coast coho ESU would be directly affected by all construction related activities. More than half of the affected vegetation (112.96 acres) would be within forested vegetation types with 16.86 acres of late successional-old growth forest and

45.82 acres of mid-seral forest would be removed within riparian zones (see table 3.5.4-30a). As discussed in section 3.5.4.2, Habitat, and data presented in table 3.5.4-10a and table 3.5.4-10b, the LWD components of most aquatic habitats in watersheds occupied by Oregon Coast coho and crossed by the Pipeline are LWD deficient and below benchmark conditions established by ODFW.

In forested habitats, conifer trees would be replanted within the construction right-of-way and TEWA outside of the 30-foot-wide maintenance corridor, which would revert to their pre-construction state over time. The 30-foot-wide maintenance corridor centered over the Pipeline would be maintained in an herbaceous/shrub state during the life of the project, assumed to be 50 years (see table 3.5.4-30b). Over the long-term, 4.55 acres through riparian LSOG forest and 11.44 acres through mid-seral forest would be maintained in an herbaceous/shrub state within riparian zones associated with Oregon Coast coho (see table 3.5.4-30b).

In areas of riparian vegetation, PCGP would neck down to a 75-foot-wide construction right-of-way at most waterbody crossings, and maintain a setback between waterbody banks and TEWAs in forested areas. Following construction, PCGP would implement measures to replant native trees and scrubs where they had been before in riparian areas, and would minimize vegetation maintenance by allowing the development of a riparian strip at least 25 feet wide to be permanently revegetated on private lands and 100 feet wide on federally-managed lands as measured from the edge of the waterbody. In forested areas, replanting of native trees would occur beyond the 25- and 100-foot-wide areas, respectively. Following planting, vegetation monitoring would occur for two to three years to ensure successful revegetation. If vegetation does not meet designated goals, additional planting would occur and monitoring would continue until the desired revegetation is achieved. Within the 30-foot-wide corridor, the plants would be maintained by periodic vegetation maintenance. As required by FERC's Plan, PCGP consulted with the NRCS, BLM, and Forest Service regarding specific seeding dates and recommended seed mixtures for the project area (see PCGP's Resource Report 7). The recommendations have been incorporated into the Pipeline project-specific ECRP (see appendix F). The ECRP describes the procedures that would be implemented to minimize erosion and enhance revegetation success for the entire Pipeline project.

Overall, restricting the low-growth vegetation area to a small portion of the total riparian right-of-way clearing would allow much of ecological function of the riparian conditions relative to coho salmon needs (e.g., shade, future LWD and organic input) to return more quickly. This would limit the overall long-term impacts of loss of riparian habitat to a small portion of each stream crossed, reducing future negative effects to coho salmon resources. Some limited intermediate term adverse effects to coho salmon habitat function would occur, primarily as a result of LWD reduction. The effect of riparian vegetation removal on water temperature and LWD are presented in the following subsections (after tables 3.5.4-30a and 3.5.4-30b).

A series of tables (M-2 through M-5, provided in appendix M) identify the areas (acres) of vegetation within riparian zones (1SPTH) affected by construction and operation of the Pipeline project across or adjacent to waterbodies with expected Oregon Coast and SONCC coho presence, by 5th field watershed. The tables identify general vegetation (forested by ageclass/ non-forested) within riparian zones that would be affected from the Pipeline crossing the waterbodies or from waterbodies adjacent to the Pipeline, as well as identify the acres of vegetation affected within the riparian zone that is federally designated critical habitat. Tables M-2 and M-4 identify areas (acres) of vegetation affected within Riparian Zones of waterbodies known or suspected to have Oregon Coast coho salmon presence, and tables M-3 and M-5 identify acres of vegetated affected within Riparian Zones of waterbodies known or suspected to have SONCC coho salmon presence.

Effects to waterbodies and Oregon Coast and SONCC coho due to removal of riparian vegetation and maintenance within the construction and operation corridor adjacent to but not crossed by the Pipeline project would be similar to effects to riparian vegetation for streams crossed by the Pipeline:

- Loss of riparian vegetation along the banks would reduce shade potentially increasing water temperatures.
- Decreased LWD recruitment in streams and on adjacent uplands, although current conditions of LWD in 5th field watersheds crossed by the Pipeline are generally undesirable.
- Removal of an important source of terrestrial food for aquatic organisms.
- Potentially increase mass slope failures and/or erosion due to surface runoff adjacent to waterbodies that could increase sediment in the waterbody.

Where vegetation is cleared from the riparian zone of a waterbody not crossed but adjacent to the Pipeline, a vegetation buffer (of some width but less than 1SPTH) adjacent to the waterbody is expected to remain. Consequently, effects from the Pipeline would be less than those described for riparian zones and associated waterbodies that would be crossed. Riparian vegetation within 1SPTH that would be maintained in a herbaceous state within the 30-foot maintenance corridor during the life of the Pipeline is included in tables M-4 and M-5. The majority of riparian vegetation affected by the Pipeline is associated with waterbodies crossed by the right-of-way (61 percent with potential Oregon Coast coho presence and 81 percent with potential SONCC coho presence), not riparian vegetation associated with waterbodies adjacent to the right-of-way.

Water Temperature

Clearing the right-of-way would remove shading vegetation from uplands and riparian areas, exposing the land and water to increased sunlight, potentially resulting in direct increases in water temperatures. Additionally, indirect increases in stream water temperatures may occur as water flows over the warmer land surface and eventually reaches the waterbody (Beschta and Taylor 1988).

The effects of water temperature on salmonid life stages have been extensively reviewed by McCullough (1999), Richter and Kolmes (2005), and others. Maximum water temperatures ranging from 22 to 24°C (71.6 to 75.2°F) limit distribution of many salmonid species. No salmonids can survive water temperatures exceeding 25°C (77°F) for extended periods (Ice 2008). High water temperatures can cause migratory species (including anadromous salmonids) to delay upstream migration (Bjornn and Reiser 1991), can decrease survival of spawners by increasing metabolic rates (Ice 2008), can positively influence rates of embryo development and emergence, but can negatively influence DO concentrations, which limit rates of embryo development (Bjornn and Reiser 1991). High temperatures inversely influence solubility of oxygen in water (Ice 2008) so that introduction of organic matter with decomposition by microorganisms reduces dissolved oxygen exacerbated by high temperatures. Along with increased fines (suspended silt and clay) and decreased relative rate of oxygen input to water (reaeration) through reduction in stream flows (Ice 2008), can adversely affect various salmonid life stages. Coho upstream migration water temperature requirements are from 7.2 to 15.6°C (46.0 to 62.1°F), spawning requirements range from 4.4 to 9.4°C (42.9 to 52.9°F), and for incubation 4.4 to 13.3°C (42.9 to 61.9°F); preferred temperature is 12.1°C (60.8°F) and upper lethal temperatures range from 26.0 to 28.8°C (86.8 to 92.8°F), depending on previous acclimation temperatures (Bjornn and Reiser 1991).

Vegetative cover that provides shade, especially during summer, is one factor that regulates water temperature. Construction across waterbodies would necessitate removal of trees and riparian shrubs at the crossing locations. Available information on the effects of pipeline construction in other regions on water temperature has found no or immeasurable change. The total width of riparian area affected by shade tree removal would be small (less than 100 feet) relative to the length of any stream crossed. In one study, construction across two coldwater, fish-bearing streams in Alberta required removing forested riparian vegetation; water temperatures at construction sites and downstream did not increase above temperatures at control sites upstream from construction (Brown et al. 2002). In the Alberta study, the highest water temperature recorded was 66°F (19°C in August). In the New York study, the highest temperature was 79°F (26°C) sometime between August and October. Similarly, water temperatures measured at four coldwater streams in New York before and during pipeline construction and for three years following construction showed no short- or long-term effects on water quality parameters, including water temperature, even though such effects were expected because streambank vegetation had to be cleared, which reduced shading (Blais and Simpson 1997).

Another recent right-of-way clearing study in Oregon found little to no effect from existing and proposed right of clearing on coldwater Cascade mountain streams (Tetra Tech 2013). Monitoring of 22 existing cleared right-of-ways for transmission lines in the Cascade region along the upper North Santiam River averaging 244 feet wide found no significant temperature (peak daily average, and daily maximum) change across the clearings compared to existing uncleared areas on each of these streams. While temperature changes did occur across the clearing (average of peak daily maximum change 0.19°F/100 feet of stream), these increases were no different from the temperature changes in the uncleared wooded areas just upstream of these clearing. While these streams did retain some vegetation in the right-of-way, they were kept relatively low to ensure no issues with the power lines. Modeling of these streams using the SSTEMP (Bartholow 2002) estimated some relatively small increases, which were generally greatest for smallest streams. The model assumed all or most vegetation would be removed from banks over a 150-foot-wide projected clearing. The results for both existing (summer 2012) and projected worst-case (likely maximum summer air temperature) environmental conditions with very conservative shade assumptions (0 and 25 percent for entire 150-foot clearings) showed an average increase of about 1.1°F (median of about 0.4°F) in the modeled maximum and maximum daily mean temperature across the assumed future clearing of these 22 streams. The small size of the streams in this study affected the model results. All but 3 of the streams had flow less than one cfs and width less than 10 feet. The three larger streams had modeled maximum temperature changes ranging from 0.0 to 0.2°F. Most of these streams had relatively low to moderate temperatures (mean maximum about 55°F); therefore, these low temperature increases were generally not expected to affect fish resources (Tetra Tech 2013).

Following requests by the Forest Service, PCGP had temperature models run by North State Resources (NSR) on six different stream segments on NFS lands in the Umpqua River basin on tributaries to East Fork Cow Creek (five crossings) and on the upper Rogue River basin on Little Butte Creek (NSR 2009). While not all of these streams are in the range of Oregon Coast ESU coho salmon, they are suitably representative of likely temperature changes that could be expected of streams of similar characteristics (i.e., width, flow, slope, vegetation, etc.) in regions where the ESU is located using these model parameters. Of the three smallest streams (with base flows <0.1 cfs, widths ≤3 feet), modeled average temperature increases ranged from 1.0 to 8.6°C (1.8 to 15.4°F) right after construction. Because these streams were so small, they likely also would have temperatures reduced rapidly downstream of the clearing from ground water inflow and likely would have no measurable effects on streams they flow into downstream. The two five- and six-foot-wide streams would have estimated maximum increases ranging from 0.4 to 0.5°C (0.7 to 0.9°F), with maximum temperatures remaining at or below 15.6°C (60.1°F) in these two streams just downstream of the crossing. These temperatures would remain well within suitable range for salmonids. The largest stream (22 feet wide) estimated increase was estimated to be 0.02 to 0.1°C (0.04 to 0.2°F) depending on the temperature model. The modeled results, based on assumptions used about rate of vegetation regrowth, found that most temperature increases remained within the first five years, but were approaching pre-project temperatures within 10 years. Conditions at other streams along the pipeline route may vary from these due to site-specific differences, but these results may be fairly representative of changes that may occur at forested streams along the route. Overall results suggest that, other than the very smallest streams where fish resources would be limited, changes in temperature from vegetation removal are likely to remain small and immeasurable having unsubstantial effects on fish resources.

Similarly, GeoEngineers (2017c) modeled thermal impacts within Fourth Field Watersheds where streams would be crossed by the Pipeline where riparian shading vegetation would be removed within the 75-foot wide construction corridor and would be affected within the 30-foot maintenance corridor for the long-term (see table 3.5.4-30b, above). Model results show a maximum predicted increase of 0.16°C at one 75 foot clearing. The analysis showed that elevated water temperatures would return to ambient levels within a maximum distance of 25 feet downstream of the pipeline corridor, based on removal of existing riparian vegetation over a cleared corridor width of 75 feet (GeoEngineers 2017c). The results are similar to the more geographically-limited results obtained by North States Resources (NSR 2009) which suggested more thermal impact. The conclusion drawn by GeoEngineers (2017c) was that the magnitude of thermal impact caused by construction would not be expected to cause a thermal barrier to fish migration.

GeoEngineers (2017c) also used the SSTEMP model by Bartholow (2002) to estimate potential temperature effects at 15 proposed pipeline crossing locations (each a 75-foot-wide clearing) along the whole route. A total of 12 of these were in the watershed range of the Oregon Coast coho salmon ESU and two are within the range of the SONCC coho salmon ESU. These sites are generally representative of watershed habitat conditions where project area coho salmon may be present along the project route although not necessarily where coho salmon are directly present. The streams selected varied in size from 2 to 85 feet wide (average 29 feet), moderately large streams, with only eight of these having a less than 10-foot flowing width. Conditions modeled were based on conditions measured during late August 2010 and did not consider maximum potential air temperatures though they were likely representative of summer conditions. The average modeled increase for these 15 streams was 0.03°F, and the maximum increase among the streams was 0.03°F. Overall, these estimated changes are relatively low. They are lower than the NSR (2009) estimates for one comparable stream, but model conditions were slightly different. The GeoEngineers model assumed a 75-foot-wide clearing, whereas the NSR model assumed a 95-foot-wide clearing and other parameter differences that would contribute to the different results.

As a rule, the effect of water temperature of a non-fish-bearing tributary on water temperature of a fish-bearing receiving stream is determined as the weighted mean of the two water temperatures, weighted by respective volumes or in-stream flows. If T_1 = temperature of tributary with F_1 = flow rate, and T_2 = temperature of receiving stream with F_2 = flow rate, then the resulting water temperature T_R at the confluence of the two waterbodies would be:

$$T_R = (T_1\ F_1 + T_2\ F_2) / (F_1 + F_2).$$

For example, Hydrofeature N is an unnamed tributary to East Fork Cow Creek crossed at MP 111.01. Pipeline construction would increase the water temperature by 8.6ºC (47.5ºF) from its base temperature of 11ºC (51.8ºF) (see NSR 2009). The water temperature would be increased to 19.6ºC (67.3ºF) but its reported summer base flow is 0.002 cfs. ODEQ measured water temperature within East Fork Cow Creek during September 1998, reported at 13.5ºC (56.3ºF). No in-stream flow data are available for East Fork Cow Creek but USGS (Gage 14309500) has measured flows in West Fork Cow Creek, reporting an average flow of 11.4 cfs during September. Using those data as to illustrate how water temperatures would be combined by the weighted average, the resulting water temperature of Hydrofeature N and the receiving stream would be T_R = (19.6ºC x 0.002 cfs + 13.5ºC x 11.4 cfs) / (0.002 cfs + 11.4 cfs) = 13.501ºC (56.302ºF). The increase of water temperature in the receiving stream by the tributary water temperature would be immeasurable [in this illustration the increase would be 0.001ºC (0.002ºF)].

PCGP has proposed supplemental riparian plantings as outlined in the ECRP (see appendix F) to help ensure that the core coldwater habitat temperature criteria are not exceeded at the maximum point of impact. These measures are designed to speed up the rate of riparian area recovery and provide more effective shade immediately following construction. Much of the riparian area would be allowed to regrow from plantings with herbaceous plants (only 10 feet wide would be maintained without some growth) and conifer and other trees (all but 30-foot width). On small streams and to a lesser extent on larger streams, even 10- to 15-foot-high trees would supply shade, reducing solar heating effects on streams. Thus plantings and vegetation regrowth in riparian areas would help moderate potential temperature increases in the short-term (a few years). PCGP would install supplemental transplanted trees on the Umpqua National Forest within the riparian areas of East Fork Cow Creek (i.e., 15 to 20 feet tall with full crowns) to increase riparian area canopy closure and placing LWD and boulders to create micro-topography within the wetted stream channel (see the ECRP). Shading from transplanted vegetation and micro-topographic features incorporated into the final grading plan are likely to reduce the heat load enough to reduce the likelihood of measurable water temperature increases. PCGP modeled the potential benefit of post project effective shade created by these mitigation measures on the Umpqua National Forest. The results of the 10-year post-project modeling time step were used to predict the benefits of the mitigation measures because the trees that would be transplanted provide at least the same shade values as predicted for this time step. The predicted water temperature changes are small, with less than a 0.3°C (0.5°F) change at the point of maximum impact, with no increase at the stream network scale (NSR 2009). Thus, based on the model, the slight effects of solar heating from clearing would gradually be reduced or completely eliminated over time, at most between 5 and 10 years. Inclusion of the measures improves the certainty that riparian area clearance and stream channel disturbance activities within the construction right-of-way would not cause measurable water temperature increases at the maximum point of impact or at the stream network scale.

Based on available information, it is anticipated that any changes in water temperature, related to 75-foot-wide right-of-way vegetation clearing at waterbody crossings, are likely to be very small and undetectable through measurements, except for possibly the very smallest and often intermittent flowing streams. Any temperature changes that may occur would gradually be reduced or eliminated over time as most riparian vegetation, from plantings and natural vegetation growth, increases in size and thus increases stream shading. Adverse effects on coho salmon resources along the route would be unsubstantial due to limited distribution of any measurable changes to regions within the 48 waterbodies with confirmed or assumed presence of Oregon Coast coho.

Large Woody Debris

A potential effect on fisheries that would result from forest clearing at pipeline crossings of waterbodies is the reduction of LWD in streams and on adjacent uplands (Harmon et al. 1986; Sedell et al. 1988). Large logs provide in-stream hydraulic complexity, which contributes to habitat complexity and the formation and maintenance of pools, riffles and other habitats which are critical to salmonid spawning and juvenile rearing. As the size of individual logs or accumulations of logs increases, the size and stability of pools that are created also increase (Beschta 1983). Riparian forests that undergo harvesting of large trees take on secondary-growth characteristics and contribute lower quantities of woody debris than unmanaged, old-growth forests (Bisson et al. 1987). However, sufficiently wide, carefully managed riparian buffers that retain a full complement of ages, sizes, and species of native trees and vegetation can ensure adequate recruitment of LWD to streams (Bisson et al. 1987; Murphy and Koski 1989).

Existing conditions associated with riparian vegetation within all 10 fifth-field watersheds in the range of the Oregon Coast coho salmon crossed by the Pipeline (see discussion related to table 3.5.4-10a and table 3.5.4-10b) are generally undesirable. Streams in the watersheds are deficient in numbers of LWD pieces per length of stream channel, in volume of LWD, and in numbers of key pieces (60 cm or greater in diameter by 12 meters or greater in length) per unit of stream length. There are too few large conifers along most stream reaches and LWD numbers, volume, and presence of key pieces tend to be below benchmark levels.

The Pipeline project would remove 16.72 acres of LSOG forest and 45.75 acres of mid-seral forest within riparian zones in watersheds occupied by Oregon Coast coho (see table 3.5.4-30a), which would affect recruitment of LWD at those sites. Of the total riparian forest affected (including clear-cut and regenerating forest stands, 28.01 acres would be removed in the Coos Subbasin, 41.01 acres within the Coquille Subbasin, and 43.10 acres within the South Umpqua Subbasin.

PCGP has proposed to use on-site mitigation for impacts to waterbodies by installing LWD at agency- and land owner-approved and appropriate areas within the construction right-of-way across certain waterbodies (see section 3.5.4.4, Conservation Measures). The use of LWD as a mitigation measure for impacts associated with in-stream construction has been documented as an effective means of creating in-stream habitat heterogeneity, reducing streambank erosion, reducing sediment mobilization (Bethel and Neal 2003), and enhancing local fish abundance (Scarborough and Robertson 2002). Placement of LWD on the streambanks and in the streams can provide slight shade and increase bank stability, while vegetation is maturing following construction. Additionally, placement of LWD in streams or on streambanks can provide habitat as substrate for benthic invertebrates, an important food source for salmonids, and also increase habitat for forage species with the creation of pools and enhancement of the salmonid rearing potential of an area (Cederholm et al. 1997; Slaney et al. 1997). Long-term losses of LWD input would largely be mitigated through riparian replanting of conifers in the right-of-way as discussed under Riparian Vegetation and Removal, above. While there may be some reduction in total stream LWD between short and long-term, the amount would be relatively small considering the total area that could be affected (most 75 feet of channel) and mitigation and enhancements that would be implemented (see Conservation Measures). LWD changes would result in minor intermediate term adverse effects to Oregon Coast coho salmon.

<u>Streambank Erosion and Streambed Stability</u>

The clearing and grading of the right-of-way during construction could increase erosion along streambanks resulting in higher turbidity levels in the waterbodies crossed. Alteration of the natural drainage ways or compaction of soils by heavy equipment near streambanks during construction may accelerate erosion of the banks, runoff, and the transportation of sediments into waterbodies. Streambank erosion, sedimentation, and higher turbidity levels related to the Project could affect aquatic resources, as discussed above. The degree of impact on aquatic organisms due to erosion would depend on sediment loads, stream velocity, turbulence, streambank composition, and sediment particle size.

The rootwad network of trees adjacent to stream supplies bank stability. Those within 25 feet of the stream are considered most important at providing the root source aiding in bank stability

(WDNR 1997). To aid in maintaining this bank stability, PCGP would cut most trees near the bank, except those in the trench line, at ground level leaving the root systems in place helping to maintain riparian stability. Roots would be removed over the trench line or from any steam banks that would need to be cut down or graded to accomplish the crossing.

To minimize these impacts, PCGP would use temporary equipment bridges, mats, and pads to support equipment that must cross the waterbody (perennial, intermittent, and ephemeral if water is present) or work in saturated soils adjacent to the waterbody. PCGP would also install sediment barriers, such as silt fence and straw/hay bales, across the right-of-way at the edge of waterbodies throughout construction except for short periods when the removal of these sediment barriers is necessary to dig the trench, install the pipe, and restore the right-of way. Practices to minimize streambank erosion are provided in section 5.0 in the ECRP (see appendix F).

The FWS expressed concerns that more detailed site-specific information on bank material, streambed composition, shoreline vegetation, and other information is needed to adequately ensure that actions occurring at a stream crossing do not substantially increase streambank erosion and streambed instability. PCGP, in response to these requests, has conducted an assessment of crossing conditions of all streams suitable for analysis based on the FWS risk matrix (GeoEngineers 2017d). The analysis results were addressed under *Suspended Sediment – Dry Open-Cut*, above. Briefly, GeoEngineers (2017d) rated 101 streams in the range of Oregon Coast coho based on the project impact potential at the crossing and the relative stream response potential at the crossing. Each crossing was rated as low, medium, or high for each of the two axes (all stream crossings were placed into one of nine categories, such as Low–Low, Low–Medium, and Medium–High). Crossing 43 of the streams would warrant application of typical construction practices; crossing 33 of the streams would warrant typical construction practices with BMPs for sensitive streambed, banks, or riparian revegetation conditions to be determined by PCGP's EI during construction; crossing four streams would warrant typical construction practices with BMPs for sensitive streambed, banks, or riparian revegetation conditions to be selected by a qualified professional prior to construction based on site-specific information from pre-construction evaluation; crossing one stream would warrant typical construction practices with enhancement BMPs such as rootwad enhancement for bank stabilization.

No crossing was rated as having both high risk of project impact potential (i.e., high risk of project impacts and high risk of site response potential) and high risk of stream and site response potential. In the range of Oregon Coast coho, Pipeline project-typical BMPs would be applied to all streams while additional site-specific BMPs would applied to the other crossing depending on their rated category of risk. Stream crossings that are unstable can ultimately adversely affect aquatic resources through loss of local habitat and impacts to downstream habitat from the addition of highly unstable sediment increasing the recovery time of the specific site to stable conditions.

In addition, substrate characteristics and physical habitat features would be determined through pre-construction surveys, and the upper one foot of existing substrate would be replaced and other physical conditions matched during reconstruction after pipe installation. Clean spawning gravel would be top dressed as appropriate and composition would be based on pebble counts or other appropriate methods on a site-specific basis. PCGP would make some exceptions to this in difficult-to-access areas, in which case native material comparable to the existing surface substrate would be used. Many of these actions would be determined prior to construction based on results of the pre-construction survey (see below) and determined by a qualified EI or suitably trained professional who would have the authority to select appropriate additional site-specific BMP construction methods, bank stability actions, revegetation types and methods to help reduce the risk of instability of the crossing and potential for future erosion (GeoEngineers 2017d).

A pre-construction survey would be conducted by a technically qualified team on all stream crossings to confirm and clarify conditions developed in the aforementioned matrix analysis. This team would be professionals qualified to assess terrestrial and aquatic habitat and the geotechnical and geomorphic conditions relative to construction across stream channels and ditches. Following these surveys, if significant changes were to occur to parameters of the risk matrix for a crossing, changes would be made to risk level and appropriate final methods of crossing and BMPs applied at each stream crossing. If any crossing is moved into the "high" project impact and "high" stream response risk matrix category, a site-specific crossing design would be developed for that site. Project construction would then move forward as described in these permit documents including implementation of special additional BMPs, as described in GeoEngineers (2017d, 2017e, and 2018a), depending on individual site conditions. For waterbodies evaluated as having Low to Moderate Project Impact Potential and Low Site or Stream Response Potential in the Risk Matrix Evaluation (the Blue Management Category, with PCGP Project Typical Construction), BMPs potentially utilized for post-construction site restoration include seeding, planting, and hydromulch or erosion control blankets to minimize surface erosion while new vegetation becomes established, as outlined in the ECRP (see appendix F). Typical site revegetation and backfill will be used to address habitat issues at these sites.

For waterbodies evaluated as having Low to Moderate Project Impact Potential and Moderate Site or Stream Response Potential in the Risk Matrix Evaluation (the Yellow Management Category, having sensitive bed, bank or riparian vegetation conditions selected by the Environmental Inspector or PCGP representative during construction), special, more robust BMPs (in addition to Project Typical BMPs) would include those targeting the streambed component (stratified backfill for high gradient streams, structural fill placement, bank graded/terraced to 3:1, geotextile reinforced slope, fiber rolls) and the streambank component (stream barbs/flow deflectors, toe rock placement, riprap placement, biotechnical "vegetation" riprap, tree revetments). As indicated by GeoEngineers (2018a), typical BMPs were developed for sites in the Yellow management category to address risks posed by bed and bank instability or degradation to existing high quality aquatic habitat. These site-specific BMPs were developed based on field observations of natural analog structures and widely accepted techniques for bank restoration, bed restoration, and aquatic habitat restoration techniques; typical designs of these BMPs are provided in Appendix B to GeoEngineers (2018a).

Waterbodies evaluated as having Low to Moderate Project Impact Potential and High Site or Stream Response Potential in the Risk Matrix Evaluation (the Orange Management Category, having sensitive bed, bank or riparian vegetation conditions selected by qualified professional prior to construction based on site-specific information from pre-construction evaluation) have the highest potential risk for short- and long-term channel stability. As described in GeoEngineers (2018a), site-specific restoration plans were developed for crossings that were assessed to be within the Orange management category based on the findings of the preconstruction surveys. The need for site-specific designs is due to more complex geomorphic or hydraulic features that increase risk of channel response to the pipeline or unique, high-value habitat features. Site-specific designs were developed using results of the preconstruction surveys, including geomorphic/hydraulic/habitat observations, topographic cross-sections, and profiles collected using a hand level and stadia rod. A written description of site-specific features and restoration priorities and design drawings are presented for each crossing in Appendix C to GeoEngineers (2018a).

For waterbodies evaluated as having High Project Impact Potential and Low to Moderate Site or Stream Response Potential in the Risk Matrix Evaluation (the Green Management Category, applying Project Typical BMPs with habitat enhancement BMPs), PCGP would use Project Typical Construction BMPs (see above). Channels in this category typically are those that disturb a greater proportion of the existing floodplain or – in narrower streams – potentially disturb more varied aquatic habitat. During site restoration, however, particular effort will be made for opportunistic habitat enhancement BMPs as detailed from observations obtained during the pre-construction survey. These enhancements could include riparian planting to improve existing habitat conditions in the floodplain, placement of large wood or rock to improve in-stream habitat, or modification of existing riprap to improve habitat. A number of the typical BMPs included in Appendix B to GeoEngineers (2018a) were designed to maintain or enhance the aquatic habitat present in the stream. These structures will often act to create complexity in the channel by scouring pools and sorting gravels as well as by providing refugia for juvenile fish. Site-specific restoration plans are provided in Appendix C (GeoEngineers 2018a).

As a follow-up measure to help ensure crossing actions would not adversely affect stream bank and channel structure, PCGP would monitor stream crossings to ensure long-term success of the restoration, maintenance of fish passage, and to identify channel erosion, scour or migration that could destabilize the site or expose the pipeline. As requested by FERC, PCGP developed a monitoring plan (GeoEngineers 2018a) following consultation with a representative from FWS and NMFS (Castro 2015). The monitoring plan would be customized, where necessary, to address risks of stream crossings identified in the Risk Analysis and those identified in subsequent preconstruction surveys.

Monitoring would consist of:

- Annual visits to all stream crossings, regardless of risk level, as part of PCGP’s monitoring of pipeline integrity. These visits would be completed by PCGP staff and would note any obvious signs of channel erosion, pipeline exposure, or major shifts in restoration elements. Potential problem areas would be subsequently visited by PCGP and a geoprofessional.
- Aerial reconnaissance would be completed annually for the life of the Pipeline and stream crossings would be reviewed for major landscape changes such as channel migration and excessive erosion. Potential problem areas would be subsequently visited by PCGP and a geoprofessional.
- Quarterly site visits to all sites in the Orange management category (sites with low-moderate project impact potential and high site or stream response potential, see GeoEngineers 2018a) for 2 years post construction to monitor revegetation success, structural stability of the restoration elements, any changes to fish passage potential resulting from the Pipeline, evidence of channel migration, erosion, head-cutting, or other stream channel movement that could influence stream or pipeline stability. Field

measurements would be taken to monitor adjustments to the channel profile and cross-sectional area.

- Annual site visits to 15 percent of all sites in the Blue management category (sites with low-moderate project impact potential and low site or stream response potential) and 100 percent of all sites in the Yellow management category (sites with low-moderate project impact potential and moderate site or stream response potential, see GeoEngineers 2018a) for 2 years post construction to monitor revegetation success, structural stability of the restoration elements, any changes to fish passage potential resulting from the Pipeline, evidence of channel migration, erosion, head-cutting, or other stream channel movement that could influence stream or pipeline stability. Field measurements would be taken to monitor adjustments to the channel profile and cross-sectional area.
- Annual site visits to 50 percent of the sites in the Yellow and 100 percent of sites in the Orange management category (see GeoEngineers 2018a) by a geo-professional in Years 3, 5, 7, and 10 to monitor revegetation success, structural stability of the restoration elements, any changes to fish passage potential resulting from the project, evidence of channel migration, erosion, head-cutting, or other stream channel movement that could influence stream or pipeline stability. Field measurements would be taken to monitor adjustments to the channel profile and cross-sectional area.
- Observations would be made during all site visits on the effects of cattle/elk browsing on restoration success, and of impacts associated with recreational use.
- Revegetation planning along the right-of-way is detailed in the ECRP. The ECRP describes monitoring and performance standards for revegetation.
- Records would be maintained annually to document any significant hydrologic events (flow or rainfall) that occur in between site visits. This shall be done to better understand the site response to moderate or large flood events. As gauging stations are extremely limited over the majority of the crossings along the Pipeline route, rainfall records would be used to identify the potential flooding that may occur in between scheduled monitoring events. These climatic events would be considered during annual monitoring when evaluating site response.
- Unscheduled site visits may be completed at stream crossings on BLM and USFS jurisdiction following localized rainfall events exceeding a 25-year rainfall intensity to monitor revegetation success, structural stability of the restoration elements, any changes to fish passage potential resulting from the Pipeline, evidence of channel migration, erosion, head-cutting, or other stream channel movement that could influence stream or pipeline stability. Field measurements would be taken to monitor adjustments to the channel profile and cross-sectional area.
- Annual reporting in Years 1, 2, 3, 5, 7, and 10 following construction would be provided to outline observations of stream crossings and any remedial action taken to restore site conditions.
- Monitoring frequency and locations may be modified in response to demonstrating site restoration success in the Annual Monitoring reports.

Overall, these actions would reduce potential adverse effects from bank and bed stability to discountable levels to listed coho salmon.

Crossing of Unstable Slopes

Potential impact to waterbodies by deep-seated landslides and shallow-rapidly moving landslide hazards on unchannelized slopes is difficult to evaluate. Slope failure near the waterbody during Pipeline operation could result in soil and sedimentation falling into the waterbody. PCGP evaluated all likely unstable areas during selection of the proposed route, and moved the route as necessary to areas considered to have low risk (GeoEngineers 2017k). There are two mapped landslide sites identified in Table B-2 in Appendix B to Resource Report 6, which are pending access with landowner permission to complete field reconnaissance to assess potential risk to the proposed pipeline. They are located near Steinnon Creek between MPs 24BR and 25BR.

Aquatic Habitat

There also are potential indirect effect to aquatic habitat from increased suspended sediment from stream crossings. The same approach utilizing TSS concentration and exposure to evaluate levels of risk to fish (Newcombe and Jensen 1996) was applied to quantifying effects of sediment on fish habitat, termed harmful alteration, disturbance or destruction (HADD) of habitat by Anderson et al. (1996). HADD risk includes concentration and exposure to sediment along with sensitivity of the habitat affected. Most likely, suspended sediment would increase embeddedness of spawning gravels with increasing habitat effects closer to the construction location.

Anderson et al. (1996), utilizing the approach of Newcombe and Jensen (1996), used sediment concentration and duration to model the level of adverse effects to fish habitat based on empirical studies.

Anderson et al. (1996) described five severity of ill effect (SE) ranks to habitat:

SE 3: Measured change in habitat preference.
SE 7: Moderate habitat degradation measured by a change in the invertebrate community.
SE 10: Moderately severe habitat degradation as defined by measurable reductions in the productivity of habitat for extended periods (months) or over a large area (kilometers).
SE 12: Severe habitat degradation as measured by long-term (years) alterations in the ability of existing habitats to support fish or invertebrates.
SE 14: Catastrophic or total destruction of habitat in the receiving environment.

The Anderson et al. (1996) HADD model utilizes the same form as the Newcombe and Jensen (1996) models, that is:

$$z = a + b\,(\log_e x) + c\,(\log_e y)$$

where z = SE score, x = duration of exposure in hours, and y = concentration of suspended sediment in mg/l. However, constants a, b, and c in Newcombe and Jensen's Model 1 for juvenile and adult salmonids (a=1.0642, b=0.6068, and c=0.7384) differ in the Anderson et al., (1996) multivariate model for SE to habitat (a=0.032, b=1.008, and c=0.978). As a consequence, for any given duration of exposure (from 2 hours to 6 hours, see table 3.5.4-27), the TSS concentration that would produce a SEV = 3 in the Newcombe and Jensen Model 1 is less than the TSS concentration that would produce a SE = 3 in the Anderson et al. HADD habitat model. Because of nonlinearities in both models, the TSS concentration that would produce a SEV = 7 in the Newcombe and Jensen Model 1 is more than the TSS concentration that would produce a SE = 3 in the Anderson et al. HADD habitat model. The SEV and SE scores are more closely aligned at lower TSS concentrations than at higher concentrations for any given duration of exposure.

Based on the models for suspended sediment concentration and duration of exposure discussed above, estimates were made for effects to habitat of Oregon Coast coho salmon. Calculated values less than SEV 7 would likely be considered to have little or no substantial effect to functional habitat, while those equal to or greater than SEV 7 likely would be substantial relative to changes in functional habitat conditions for coho salmon. In this BA, similar levels of effect due to TSS concentrations and durations of exposure are assumed to apply to coho salmon.

During a failure of dry open-cut construction, TSS concentrations of up to 361 mg/l over background TSS concentrations could last for 6 hours (see table 3.5.4-27). If that same concentration is applied in the Anderson et al. HADD model with duration of 6 hours, the SE score is >7 but ≤8, indicating slightly more damage to habitat than "moderate habitat degradation measured by a change in the invertebrate community." To ensure a SEV score less than 7, in-stream work to repair a failed containment structure would likely have to be restricted to less than 4 hours. Thus, unless crossing failures occur in these stream crossings, there would be no substantive adverse effects to coho salmon habitat from sediment generated during stream crossings.

Freshwater Stream Invertebrates

Substrates downstream from in-stream construction sites could be impacted by sediments. Mayflies, caddisflies, and stoneflies prefer large substrate particles in riffles and are adversely affected by fine sediment deposited in interparticulate spaces (Cordone and Kelley 1961; Waters 1995; Harrison et al. 2007). Fish and benthic macroinvertebrate abundance downstream of pipeline construction sites have been reported as short-term reductions following construction-generated suspended sediment (Reid and Anderson 1999). Macroinvertebrate abundance and community composition are highly related to the degree to which substrate particles are embedded by fine material (Birtwell 1999).

Fish emigrate from construction sites and benthic taxa drift downstream to sites where sediment deposition has not affected habitat suitability (Reid and Anderson 1999). In Ontario, stream crossing construction using fluming produced less turbidity and sediment concentrations downstream than construction by wet open cutting streams; wet open cutting resulted in a significant decrease in aquatic invertebrates downstream three days post-construction (Baddaloo 1978 cited in Gartman 1984). One year after construction there were no significant differences in benthos numbers. Reid et al. (2008) summarized the results of nine wet open-cut pipeline stream crossing studies found similar results and noted all measured effects to downstream stream invertebrate population abundance or diversity (six of nine studies) were less than a year in duration with three studies having no measured effects on invertebrate abundance. In general, the percentage of type of stream benthos and invertebrate taxa affected by construction of the Pipeline would be in proportion to their abundance during the season of construction, which is likely to be relatively high as crossings would occur during the summer growing season.

Rapid colonization by benthic organisms of disturbed substrate following pipeline construction has been demonstrated elsewhere. In Pennsylvania, samples taken before and 30 days after pipeline construction revealed rapid recolonization of the disturbed and newly-exposed stream substrate by benthic macroinvertebrates (Gartman 1984). Similarly, the number and diversity of aquatic invertebrate taxa in coldwater streams in New York State were unchanged two to four years following pipeline construction from those measured prior to construction (Blais and Simpson 1997). Additionally, most studies of effects on stream invertebrates are based on wet open-cut crossings, which normally have much higher suspended sediment concentrations than the isolated dry stream crossing methods that would be used by the proposed Pipeline project. Therefore, the overall level of effect of the pipeline crossings on freshwater stream invertebrates, unless crossing sealing failures occur, would be even less than that noted by literature and would not result in substantial reduction in growth or survival of listed coho salmon individuals.

Hydrostatic Testing

Water would be required on a one-time basis near the end of construction to hydrostatically test the pipeline. Potential impacts associated with hydrostatic testing include entrainment of fish, reduced downstream flows, and impaired downstream uses if test water is withdrawn from surface waters, and erosion, scouring, and a release of chemical additives occur as a result of test water discharge. PCGP would obtain its hydrostatic test water from commercial or municipal sources or surface water rights owners, the sources of which are lakes, impoundments, and streams.

There are six locations within the range of the Oregon Coast coho ESU where water would be withdrawn for hydrostatic testing and/or dust control. Oregon Coast coho are present at only one location – at the crossing of the South Umpqua River. An estimated total of 19,508,387 gallons would be withdrawn from the six locations.

There are 19 proposed hydrostatic test break sections that are within range of Oregon Coast coho ESU. Of those, 10 hydrostatic test break sections are within 0.5 mile of a waterbody with known Oregon Coast coho habitat. Distances separating test break from waterbodies range from 100 feet (Monkey Ranch Gulch) to over 2,000 feet. There may be some risk of discharged hydrostatic test water accidentally entering the waterbodies with designated critical habitat. PCGP developed a Hydrostatic Test Plan (see appendix U) in consultation with the BLM and Forest Service as well as the Center for Lakes and Reservoirs and Aquatic Bioinvasion Research and Policy Institute (Portland State University) and ODEQ. This Plan outlines the general hydrostatic testing process and describes the BMPs to minimize or avoid potential effects that could result from hydrostatic testing, including accidental release of test water. One of the purposes of the plan was to develop BMPs to prevent the potential transfer of invasive species and pathogens from one watershed to another.

The discharge volume at each site ranges from about 0.2 to 3.3 million gallons at rates ranging from several hundred to several thousand gallons per minute. Total water used would be about 62 million gallons, with about half from impoundments or lakes, and the rest from streams, including South Umpqua River, Rogue River, North Fork Little Butte Creek, and Klamath River. Within the range of Oregon Coast ESU of coho salmon, there are six potential water sources. Four of the sources are water district sources while two are on the South Umpqua River which is not a district water source.

PCGP would minimize the potential effects of hydrostatic testing on these watersheds by adhering to the measures in its Hydrostatic Testing Plan (see appendix U), including screening intake hoses to prevent the entrainment of fish and other aquatic organisms, meeting NMFS screening criteria, and regulating the rate of withdrawal to avoid adverse impact on aquatic resources or downstream flows. Where test water cannot be returned to its withdrawal source, the water would be treated with a mild chlorine treatment and discharged to an upland location (at least 150 feet from streams with no direct discharge features) through a dewatering structure at a rate to prevent scour and erosion and to promote infiltration. PCGP would obtain all necessary appropriations, withdrawal, and discharge permits through the OWRD. With the implementation of the Hydrostatic Testing Plan and BMPs, and obtaining required permits, adequate measures would be in place to prevent direct or indirect effects to Oregon Coast coho salmon that may be in these stream systems.

One of the responsibilities of the EI is to oversee and confirm the activity to be in compliance with the requirements of FERC's Upland Plan and Wetland and Waterbody Procedures and all other environmental permits and approvals, including the multiple plans comprising the POD (see section 4.0 in the ECRP in appendix F). For example, this would include compliance with the Oregon Water Resources water appropriation Limited Use license permit conditions, which specify water withdrawal rates and volumes from specific sources. The EI would document that these permit conditions are followed and oversee that contractor's water withdrawal pumps used to withdraw surface water would be screened according to NOAA Fisheries screening criteria to prevent entrainment of aquatic species. When pumping water from a source, the pump head would be submerged and maintained on average at the center of the water column so as to prevent sucking in sediments and/or algae lying at the water level surface or sediments resting on the bed of the waterbody. The EI would also work with contractors so that the targeted ramping rate would be managed such that there is no significant decrease of river flows.

Aquatic Nuisance Species

Nonindigenous Aquatic Species (NAS) are aquatic species that degrade aquatic ecosystem function and benefits, in some cases completely altering aquatic systems by displacing native species, degrading water quality, altering trophic dynamics, and restricting beneficial uses (Hanson and Sytsma 2001). Currently, there are 180 reported NAS in Oregon, of which 134 are documented within the USGS hydrologic basins crossed by the proposed Pipeline (USGS 2017).

In the riverine environments crossed by the Pipeline, largemouth bass and smallmouth bass, introduced as recreational species, prey on juvenile sockeye, coho, and Chinook salmon (Tabor et al. 2007). Management priorities in Oregon concentrate on the NAS whose current or potential impacts on native species and habitats, and economic and recreational activity in Oregon, are known to be significant (Hanson and Sytsma 2001). Some of the major potential freshwater invasive species are mussels including the zebra and quagga mussels (*Dreissena polymorpha*, and *Dreissena rostriformis bugenisis*), as well as Chytrid fungus and other species of concern.

Management priorities in Oregon concentrate on the species whose current or potential impacts on native species and habitats and economic and recreational activity in Oregon are known to be significant, known as aquatic nuisance species (Hanson and Sytsma 2001).

Aquatic nuisance species could potentially be introduced into Pipeline project area waters by basin transfer through hydrostatic testing or be carried on equipment that is moved from outside of the region or between basins. PCGP has developed BMPs and guidelines to avoid the potential spread of the aquatic invasive species and pathogens of concern (see *Hydrostatic Testing Plan*, appendix U) in consultation with the BLM and Forest Service as well as the Center for Lakes and Reservoirs and Aquatic Bioinvasion Research and Policy Institute. If determined to be feasible for hydrostatic testing requirements, all water used in hydrostatic testing would be returned to its withdrawal source location after use; however, cascading water from one test section to another to minimize water withdrawal requirements may make it impractical to release water within the same watershed where the water was withdrawn. If it is not possible to return the water to the same water basin from where it was withdrawn, PCGP would employ an effective and practical water treatment method (chlorination, filtration, or other appropriate method) to disinfect the water that would be transferred across water basin boundaries. The hydrostatic test water would be treated after it is withdrawn and prior to hydrostatic testing.

PCGP would implement a three-step BMP treatment process to prevent the potential spread of invasive species and forest pathogens from non-municipal surface water sources used during hydrostatic testing. The hydrostatic test water treatment process would incorporate screening/filtration during water withdrawal, chlorine treatment, and upland discharge at least 150 feet from wetlands or waterbodies with no direct discharge to these features. All hydrostatic test water would be released through a dewatering device such as a straw bale structure or sediment bag, in a manner to promote infiltration. Further, all hydrostatic release locations would be monitored after construction to ensure noxious weeds have not become established.

As explained in the Hydrostatic Test Plan, PCGP proposes to use a treatment of 2 ppm or 2 mg/L of free chlorine residual with a detention time of 30 minutes to treat all non-municipal surface waters that would be used as a water source for hydrostatic testing purposes. Chlorinated water would be released according to the Oregon Department of Environmental Quality criteria to prevent water quality impacts, potential effects to aquatic species, and to minimize potential impacts to sensitive areas.

Mobilization of Contaminated Substances

The U.S. Forest Service reported that naturally occurring mercury exists in the vicinity of the Mars Fraction lode claim located near MP 108.7 (GeoEngineers 2017k). Natural-occurring mercury is present in the disrupted soil regolith and underlying bedrock strata throughout the upper reaches of the East Fork Cow Creek watershed. Geochemical analysis of six soil samples collected along a 2,000-foot section of a previously proposed route that crossed partly through the historic Thomason mining claims near the East Fork Cow Creek has been determined to have very low concentrations of natural-occurring mercury mineralization (GeoEngineers 2017k). The Pipeline location subsequently was rerouted approximately 2.500 feet from where the samples were taken. GeoEngineers (2017k) opined that the soils underlying the currently proposed crossing of the East Fork Cow Creek are unlikely to have concentrations of naturally occurring mercury exceeding those measured in samples obtained from the previous crossing location and most likely will have lower levels.

PCGP developed the ECRP with a number of temporary and permanent erosion control measures to minimize the potential for sediment to enter wetlands or waterbodies (see appendix F). As described in Attachment 1 to the Contaminated Substance Discovery Plan, the temporary or short-term erosion control measures/BMPs are to be employed throughout the construction phase and would be routinely monitored by an EI or authorized company representative.

The following recommendations were developed by the Forest Service in consultation with ODEQ. They were also discussed and agreed upon at the February 2, 2010 meeting to review the Contaminated Substances Discovery Plan:

- Within Riparian Reserves for all hydrologic features crossed by the pipeline between MP's 109 and 110 (figure. 5, Contaminated Substances Discovery Plan) provide 100% post-construction ground cover on all disturbed areas. Wood fiber is the preferred material. In addition, construct water bars at 50-foot intervals.
- At hydrologic features G, J, and K (figure. 5, Contaminated Substances Discovery Plan) assure that erosion control measures are in place before the fall rains and monitor for rilling, gullying and other forms of active erosion that may transport sediment into the aquatic environment. If rilling or gullying is occurring that may result in sediment transport into the aquatic environment, improve erosion control measures to preclude sedimentation.
- Inspect the construction corridor for sedimentation after each significant storm event (which would be more frequently than a bank-full event) or whenever there is a visual sediment plume downstream. If the sediment source is originating from the pipeline corridor, improve erosion control measures to preclude sedimentation.

The summary of the report in Attachment 1 to the Contaminated Substance Discovery Plan states that the proposed pipeline construction activities within the upper East Fork Cow Creek watershed are not anticipated to disturb and expose soils and bedrock strata that contain more than low amounts of natural occurring mercury mineralization, and any sediment that is generated is not likely to reach the aquatic environment due to implementation of short-term and permanent mitigation measures outlined in PCGP's ECRP and as listed in Attachment 1 to the Contaminated Substance Discovery Plan. Also, Galesville Dam, approximately 18 miles downstream of the crossing and at the boundary of Upper Cow Creek watershed, is a complete barrier to fish passage and the Oregon Coast coho salmon no longer occur in this watershed.

Fuel and Chemical Spills

Fisheries habitats could be adversely affected if petroleum products of a substantial quantity were accidentally discharged into aquatic environments. Such materials are toxic to algae, invertebrates and fish. Of the products likely to be present during construction, data compiled from a wide range of sources indicate that diesel fuels and lubricating oils are considerably more toxic to aquatic organisms than other, more volatile products (gasoline) or heavier crude oil (Markarian et al. 1994). Release of diesel fuel in freshwater habitats significantly reduced aquatic invertebrate densities and species richness at least 3 miles downstream but invertebrate densities recovered within a year (Lytle and Peckarsky 2001). Impacts to aquatic habitats that primarily affect aquatic substrates – hence spawning, incubating and rearing habitats – can remain for much longer periods (Markarian et al. 1994).

Equipment used for construction across waterbodies could potentially release hydraulic fluid comprised of a variety of compounds, the most common of which are mineral oil-based, organophosphate esters and polyalphaolefins (HHS 1997). Release from machinery can occur through faulty seals, hoses, sumps and reservoirs, or general system failure. Components of mineral oil and polyalpaolefins do appear to bioaccumulate in animals whereas larger molecular constituents in organophosphate esters can concentrate in fish, primarily partitioning in fat tissue (HHS 1997). In general, toxicity of organophosphate esters is greater than either mineral oil or polyalphaolefin-based hydraulic fluids when inhaled, ingested, and in contact with the skin for humans. Toxicities have not been clearly described for aquatic invertebrates or fish and would be dependent on specific chemical components (HHS 1997).

Inadvertent spills of fluids used during construction, such as fuels and lubricants, could contaminate wetland soils and vegetation if not sufficiently contained. To minimize the potential for spills and any impacts from such spills, PCGP's SPCCP (see appendix L) would be implemented. In general, hazardous materials, chemicals, fuels, and lubricating oils would be not be stored, nor would refueling operations or concrete coating activities be conducted within 100 feet (150 feet on BLM and Forest Service lands) of a wetland or waterbody in accordance with FERC's *Procedures* (see appendix C) and the SPCCP (see appendix L) except where no reasonable location is possible and additional containment steps have been taken. The SPCCP would be updated with site-specific information prior to construction. Adherence to these plans and procedures would results in effects to Oregon Coast coho salmon that would be discountable.

Streambed Scour

Fluvial erosion represents a potential hazard to the Pipeline where streams are capable of exposing the pipe as a result of channel migration, avulsion, widening, and/or streambed scour. The principal hazard resulting from channel migration and streambed scour is complete or partial exposure of the Pipeline within the channel from streambed and bank erosion or within the floodplain from channel migration and/or avulsion. To address this potential hazard, PCGP completed a channel migration and scour analysis (GeoEngineers 2017i and GeoEngineers 2018b). In this analysis, stream crossings along the route were evaluated with respect to potential future risk to the Pipeline that could result from channel bed scour and/or lateral migration. The evaluation was conducted in two phases: Phase I involved a desk top evaluation and small field investigation in which all stream crossings were ranked for potential risk; Phase II involved detailed field investigation and analyses of those stream crossings that were concluded to pose risk to the Pipeline based on the Phase I study.

Minimizing the effects of migration and scour hazards to the Pipeline can be accomplished with the following (GeoEngineers 2017i and GeoEngineers 2018b):

- At each channel crossing, bury the pipe below the estimated depth of streambed scour. Where bedrock is encountered at shallower depths than the estimated scour depth, the elevation of competent bedrock represents the limit of scour.
- Where feasible, place the pipe into bedrock.
- Within floodplains adjacent to migrating channels, bury the pipe below the projected depth of the channel thalweg within the 50-year channel migration zone.

The Pipeline would be designed to protect the integrity of the pipe, which may include increasing the depth of cover to more than the 5-foot minimum to accommodate the potential for long-term scour and bank stabilization. At a minimum, PCGP would design all waterbody crossings to meet U.S. Department of Transportation standards (CFR 49 Part 192). Additional depth would be evaluated and considered based on GeoEngineers' (2018b) Channel Migration and Scour Analysis or other site-specific investigations, considering the final route alignment. From the results of the Channel Migration and Scour Analysis, PCGP would bury the pipe below the estimated 100-year scour depth or into competent bedrock, whichever is shallower.

Effects to Hyporheic Exchange

The hyporheic zone is defined by the extent of surface-subsurface mixing, the hyporheic exchange that moves surface water into the surrounding alluvium and back to the river again through the porous sediment surrounding a river (Tonina and Buffington 2009). The downwelling flows of surface water supply the wetted hyporheic zone with dissolved oxygen, which sustains organisms in the aerobic environment but decomposition of organic materials in the hyporheic zone may deplete oxygen concentrations in return flows to the surface (Findlay et al. 1993; Tonina and Buffington 2009). Alternatively, nutrient enrichment to surface waters occurs with hyporheic exchange by upwelling flows (Valett et al. 1990). For example, hyporheic flow is important for surface water/groundwater interactions that influence bull trout spawning sites and use of other habitats (e.g., juvenile rearing, migration) (FWS 2005h) and presumably those of other salmonids.

GeoEngineers (2017j) developed a ranking procedure to qualitatively evaluate site conditions at waterbody crossings and the probable influence on hyporheic flow and whether a stream channel will have an active and functional hyporheic zone. The procedure assigns a value of 1 to 5 for different criteria: alluvial vs. bedrock substrate, substrate sediment size, stream flow period, presence of an upstream drainage basin, and channel gradient vs. percent drainage area contribution to the 5th field HUC upstream from the pipeline crossing. The procedure includes weighting factors emphasizing importance of some criteria over the others. In the range of Oregon Coast coho, there was a total of 7 stream crossings evaluated in the Coos Subbasin, 37 evaluated in the Coquille Subbasin, and 67 stream crossings evaluated in the South Umpqua Subbasin. None of the crossings in the Coos Subbasin and only 1 crossing in the Coquille Subbasin (Middle Fork Coquille River Watershed) was evaluated as having high sensitivity to hyporheic zone alteration. Further, 8 crossings in the South Umpqua Subbasin (2 in Myrtle Creek, 3 in Clark Branch-South Umpqua River, and 1 each in the remaining three watersheds crossed) were evaluated as having high sensitivity to hyporheic zone alteration. In all, 30 stream crossings in the three subbasins had moderate sensitivities and the remaining 62 crossings scored low sensitivity to hyporheic zone alteration.

Construction of the pipeline using dry open cut construction would require removal of native streambed and bank material from the stream. The subsequent burial of the pipeline would involve replacing those native materials back in the streambed and stream banks. At crossings with steep natural stream banks (e.g., slopes steeper than 3H:1V [horizontal to vertical]), additional stabilization measures such as compaction of backfill may be required that could locally alter stream bank permeability from pre-construction conditions. Removal and replacement of native stream material has the potential to locally disrupt the structure and organization of the hyporheic zone in the immediate area of the pipeline crossing. However, such alterations would be expected to be minimal relative to adjacent unaffected streambed and stream banks and could either increase or decrease permeability over an extremely narrow segment of a stream channel, up to 12 feet in width at the maximum trench width. Local disruption of hyporheic function by construction and presence of the pipeline would not be expected to result in measureable effects to dissolved oxygen and/or nutrient enrichment and would not adversely affect coho.

BMPs that reduce the potential impacts to the hyporheic zone include the following:

- Native material that is removed from the pipeline trench during excavation across stream channels will be used to backfill once the pipe is in place in order to minimize potential changes to preconstruction permeability.
- Trench plugs will be installed at the base of slopes adjacent to wetlands and waterbodies and where needed to avoid draining of wetlands or affecting the original wetland or waterbody hydrology.

While the potential impact of pipeline construction on hyporheic exchange is considered to be low at all stream crossings considering the proposed construction methods, PCGP proposes these additional measures to further reduce the potential for even localized impacts to water quality from hyporheic exchange at the stream crossings identified as having high hyporheic sensitivity (Appendix A to GeoEngineers 2017j):

- Document streambed stratigraphy prior to construction if possible, or if not possible, during construction to aid in site restoration. Such documentation will be conducted by staff trained in recognizing and observing river channel processes. If done during construction, this may be performed by the EI after receiving suitable training.
- Segregate active streambed gravels and cobbles from underlying streambed materials (including fractured bedrock) to their natural depth and replace gravels/cobbles to this natural pre-construction depth.
- Below active stream gravels, replace native material in a manner to match upstream and downstream stratigraphy and permeability to the maximum extent practicable.

Runoff from Permanent, Temporary, Existing Access Roads (PARs, TARs, EARs), and TEWAs

Run-off from PARs, TARs, EARs, and TEWAs can result in sediment delivery affecting stream supporting Oregon Coast coho. PCGP proposes to construct three new TARs and four new PARs within the range of Oregon Coast coho (table 3.5.4-31). Potential for sediment delivery to streams following construction of the roads was evaluated by applying sediment and drainage assessment components of the Washington Road Surface Erosion Model or WARSEM (Dube et al. 2004) which has been previously applied in Oregon (Surfleet et al. 2011). Specific WARSEM components have been used to evaluate levels of risk for delivery of sediment to streams nearest each TAR and PAR as well as nearest streams supporting ESA-species. Two TARs have low risks of sediment delivery to any stream but only one TAR has a low risk of delivery to an ESA stream – North Fork Little Butte Creek which supports Oregon Coast coho with designated critical habitat. None of the other proposed TARs and PARs have any risk of sediment delivery to streams closest to new road sites.

Similar risk analyses were conducted for portions of EARs that are known to occur within 1SPTH of streams with designated critical habitat for coho and other streams known or assumed to provide habitat for coho in the two ESUs. Finally, TEWAs that are proposed within 1SPTH of critical habitat for coho were evaluated for risks of sediment delivery to coho critical habitat. BMPs)proposed by PCGP that would be applied to PARs, TARs, EARs, and TEWAs to prevent sediment delivery in coho critical habitats and other coho-bearing streams are summarized from the ECRP (appendix F to the APDBA).

The risk analysis utilizes four modelling components required for sediment and drainage assessment as applied in WARSEM. The components that were evaluated for each TAR/PAR include:

- Dominant lithology – information source: Oregon Department of Geology and Mineral Industries, Oregon Geologic Data Compilation 6 (OGDC-6 geodatabase) available from http://www.oregongeology.org/sub/ogdc/index.htm. Dominant lithology coinciding with locations of each PAR or TAR was evaluated at each location.
- Road gradient – evaluated gradient at each PAR or TAR on topographic map using contour lines (rise divided by run) if road gradient >5 percent grade. If less than 5 percent, gradient was noted as 0 – 5%.
- Annual rainfall – information source: Western Regional Climate Center, Western U.S. Climate Historical Summaries available from https://wrcc.dri.edu/Climsum.html. Annual raifal at each location was evaluated by adjusting the average total precipitation for snowfall during the period of record for National Weather Station closest to each PAR or TAR.
- Delivery – evaluated closest distance of each PAR or TAR to any stream segment (perennial or intermittent, using National Hydrography Dataset, available at https://nhd.usgs.gov/data.html) and to each stream segment supporting ESA-listed fish using ODFW Oregon Fish Habitat Distribution Data available at https://nrimp.dfw.state.or.us/nrimp/default.aspx?pn=fishdistdata. In addition, distances of nonforested and forested vegetation intervening between road and stream segment were measured using GIS.

Technical documentation (Appendix A) in Dube et al. (2004) was used to evaluate levels of risk for erosion and sediment delivery contributed by each of these four site-specific components at each proposed PAR or TAR.

In addition to site-specific conditions, PCGP has specified road lengths and widths for each proposed PAR or TAR. Although road surfacing has not been specified, PCGP has proposed surfacing enhancements as necessary in Section 2.3 of the Transportation Management Plan (see POD). Road length, width, and surfacing are required components for use in WARSEM as well as daily average traffic volume, which is currently unknown but may be hypothesized using categorical traffic levels in technical documentation for WARSEM (Appendix A, in Dube et al. 2004) and a road age factor which is irrelevant to the evaluation of risk for sediment production since none of the proposed roads have been constructed.

The following components required for WARSEM cannot be evaluated for the PARs and TARs:

- Road prism geometry
- Cuttslope height
- Cuttslope cover
- Drainage ditch width
- Drainage ditch condition

WARSEM estimates the average annual amount of road surface erosion that is delivered to a stream from each road segment modeled by using calculations based on empirical relationships derived from road erosion research (Dube et al. 2004). The model uses the following formulas to calculate road surface erosion and delivery to a stream:

Total Sediment Delivered to a Stream from each Road Segment (in tons/year) = (Tread & Ditch Sediment + Cutslope Sediment) x Road Age Factor

Tread & Ditch = Geologic Erosion Factor x Tread Surfacing Factor x Traffic Factor x Segment Length x Road (Tread + Ditch) Width x Road Gradient Factor x Rainfall Factor x Delivery Factor

Cutslope = Geologic Erosion Factor x Cutslope Cover Factor x Segment Length x Cutslope Height x Rainfall Factor x Delivery Factor

New TARs and PARs. Some of the relevant information used to derive various "Factors" necessary for WARSEM are provided in the tables, below. Percent gradient at locations of proposed TARs and PARs and the associated Road Slope Factor is provided in table 3.5.4-31. The gradient of a road segment influences the erosion rate. Three Road Slope Factors are used in WARSEM and apply to gradients estimated in table 3.5.4-31. The steepest gradient estimated for any proposed road was 20% for TAR-101.70 which corresponds to a Road Slope Factor of 2.5. Except for that road, the other the proposed road locations are on relatively flat terrain with gradients estimated from 0 to 5% and Road Slope Factors of 0.2.

TABLE 3.5.4-31

Location and Physical Characteristics for Proposed TARs and PARs in Range of Oregon Coast Coho.

Road Identification	Fifth Field Watershed	Latitude	Longitude	Length (feet)	Width (feet)	Surface Area (acres)	Gradient (Road Slope Factor) a/
TAR-27.06	North Fork Coquille River	43°10'36.344"N	124°1'37.944"W	1,500	20	0.69	0 to 5% (0.2)
TAR-29.92	East Fork Coquille River	43°9'28.876"N	123°59'25.81"W	2,249	16	1.03	0 to 5% (0.2)
TAR-88.69	Days Creek-South Umpqua River	42°59'17.891"N	123°5'57.096"W	416	20	0.19	0 to 5% (0.2)
TAR-94.81	Days Creek-South Umpqua River	42°55'55.686"N	123°2'14.79"W	114	20	0.05	0 to 5% (0.2)
TAR 101.70	Days Creek-South Umpqua River	42°51'29.524"N	123°0'11.673"W	1,517	25	0.69	20% (2.5)
PAR-15.07	Coos Bay-Frontal Pacific Ocean	124°8'11.584"N	43°20'13.082"W	258	25	0.15	0 to 5% (0.2)
PAR-29.48	East Fork Coquille River	123°59'44.13"N	43°9'23.464"W	85	25	0.04	0 to 5% (0.2)
PAR-48.58	Middle Fork Coquille River	123°42'58.591"N	43°3'2.731"W	222	25	0.13	0 to 5% (0.2)
PAR-59.58	Olalla Creek-Lookingglass Creek	123°31'13.339"N	43°4'46.221"W	105	25	0.07	0 to 5% (0.2)
PAR-71.46	Clark Branch-South Umpqua River	123°19'41.662"N	43°3'13.832"W	692	25	*0.84*	0 to 5% (0.2)
PAR-80.03	Myrtle Creek	123°11'35.585"N	43°3'6.44"W	92	25	0.05	0 to 5% (0.2)
PAR-94.66	Days Creek-South Umpqua River	123°2'26.5"N	42°55'58.579"W	501	25	0.29	0 to 5% (0.2)

a/ Road Slope Factors: 0.2 for gradients of <5%; 1.0 for gradients of 5-10%; 2.5 for gradients >10%. See Table A-6, Appendix A, Dube et al. 2004

Erodibility of a road segment is related to soil characteristics at the site location which are related to the parent lithology and weathering. Relative erodibility for different rock types of different geologic ages that are associated with proposed TARs and PARs are provided in table 3.5.4-32 as the Geologic Erosion Factor corresponding to each lithology. The highest Geologic Erosion Factor (5) is associated with Quaternary and Tertiary volcanic ash and tuff as well as with weathered granite and other intrusive rocks. Deeply weathered sedimentary rocks that degrade to silt and sand also have the highest Geologic Erosion Factor (5). Weathered schist or gneiss from the Tertiary and older formations have moderate Geologic Erosion Factor (2), and others in table 3.5.4-32 have low Geologic Erosion Factor (1).

Rainfall strongly influences erosion and sediment transport. Instead of using the PRISM climatic model as applied in WARSEM), data from NWS cooperating stations closest to each proposed TAR and PAR were used to evaluate average annual rainfall (average monthly precipitation adjusted for average monthly snowfall, described in Equation 6, Appendix A, Dube et al. 2004) for each station's period of record. That information is provided in table 3.5.4-32. A Rainfall Factor, derived from the average annual rainfall at the closest NWS station, is computed from Equation 7, Appendix A, Dube et al. (2004) and provided in table 3.5.4-32. In general, average annual rainfall and Rainfall Factors for proposed TARs and PARs decline with distance along the Pipeline route from west to east.

TABLE 3.5.4-32

Surface Lithology and Average Annual Total Rainfall Estimated at the
National Weather Service Station (NWS) Closest to Each Proposed TAR and PAR in Range of Oregon Coast Coho.

Road Identification	Dominant Lithology a/	Geologic Erosion Factor b/	Closest NWS Station (NWS Number) c/	Period of Record	Station Distance to Road (miles)	Average Annual Rainfall d/ (inches)	Rainfall Factor e/
TAR-27.06	Quaternary fluvial terrace deposits	high (5)	Dora 2 W (352370)	1969-1999	1.4	59.15	**7.3**

b/ Geologic Erosion Factor surmised from Figure A-1 and Table A-1 in Appendix A, Dube et al. 2004.
c/ Closest NWS Station (with Cooperator Number) based on coordinates provided in individual station data, available from Western Regional Climate Center, Western U.S. Climate Historical Summaries (available from https://wrcc.dri.edu/Climsum.html).
d/ Average Annual Rainfall derived from average monthly precipitation adjusted for average monthly snowfall, described in Equation 6, Appendix A, Dube et al. (2004).
e/ Rainfall Factor derived from the average annual rainfall at the closest NWS station, computed using Equation 7, Appendix A, Dube et al. (2004).

The Delivery Factor is a key component of WARSEM and subsequent estimation of risks by erosion and road-generated sediments to aquatic resources. Sediment transport is dependent on the slope of the hillside, infiltration capacity of the soils, volume and depth of runoff water, and obstructions on the hillside (e.g., effectiveness of vegetative buffers at trapping sediment) that would slow runoff water and trap the sediment (Dube et al. 2004). While roads farther than 200 feet from a stream are assumed not to deliver sediment to streams unless a gully exists that allows for transport of sediment from the road to the stream, roads within 100 to 200 feet of a stream are assumed to allow for delivery of 10 percent of produced sediment; roads <100 feet from a stream allow for delivery of 35 percent of produced sediment, and drainage from a road to a stream allows for 100 percent of produced sediment (see Table A-10, Appendix A, Dube et al. 2004).

This simplified scheme identifies four levels for the Road Delivery Factor in WARSEM: 0, 10, 35, and 100 (see table 3.5.4-33). Although vegetation characteristics are not factors in WARSEM, distances through nonforested and forested vegetation that intervene between each proposed road and the closest stream (and closest stream supporting ESA species) are included in table 3.5.4-33. The highest Road Delivery Factor in table 3.5.4-33 is 100 (indicating delivery of 100 percent of sediment produced by the new road) for PAR-15.07 which crosses Laxstrom Gulch, a tributary to Stock Slough and a waterbody that supports Oregon Coast ESU coho which is designated critical habitat for the ESU. PAR-71.46 also crosses an intermittent tributary to the South Umpqua River (Road Delivery Factor = 100), but the tributary does not support ESA-listed species. None of the other TARs and PARs are <100 feet from any stream that supports Oregon Coast coho.

TABLE 3.5.4-33

Estimated Risks for Sediment Delivery to Any Closest Stream and Closest Stream with ESA Species from Each Proposed TAR and PAR in Range of Oregon Coast Coho with Distances of Vegetation Intervening between Road and Stream

Road Identification	Closest Stream (distance)	Flow a/	Intervening Vegetation (distance)	Road Delivery Factor b/	Closest ESA Stream (distance)	Intervening Vegetation (distance)	Road Delivery Factor b/

a/ Flow: P = Perennial, I = Intermittent/Ephemeral
b/ Road Delivery Factor: in WRSEM = 0, 10, 35, and 100 see Table A-10, Appendix A, Dube et al. (2004).

TABLE 3.5.4-33

Estimated Risks for Sediment Delivery to Any Closest Stream and Closest Stream with ESA Species from
Each Proposed TAR and PAR in Range of Oregon Coast Coho with Distances of Vegetation Intervening between Road and Stream

Road Identification	Closest Stream (distance)	Flow a/	Intervening Vegetation (distance)	Road Delivery Factor b/	Closest ESA Stream (distance)	Intervening Vegetation (distance)	Road Delivery Factor b/

c/ Supporting Oregon Coast ESU Coho and Critical Habitat

The products of three site-specific erodibility factors - Road Slope, Rainfall, and Geologic Erosion factors – are provided in table 3.5.3-31. The product of the three factors represents a calculated level of risk for erosion from each road's surface and has been ranked as Low (product <1), Moderate (product from 1 to 5), and High (product >5). The largest three factor product is 8.7 for PAR-15.07 due to a high Rainfall Factor and high Geologic Erosion Factor. Table 3.5.4-34 also includes the Road Delivery Factor for any stream closest to each proposed road. The four factor products (including the three Site Erodibility Factors and Road Delivery factor for any closest stream) have been ranked as None (product of 0), Low (product >0 to 20), Moderate (product >20 to 50), and High (product >50).

The risk analysis indicates there are two PARs (PAR-15.07 and PAR-71.46) with high risks of sediment delivery to any stream but only one PAR (PAR-15.07) has a high risk of sediment delivery to an ESA stream with critical habitat (Laxstrom Gulch). Three TARs (TAR-27.06, TAR-88.69, and TAR-94.81) have a moderate risk of sediment delivery to any stream and two of them have same moderate risk of delivery to ESA streams that support Oregon Coast coho with designated Critical Habitat (Middle Creek and Days Creek).

TABLE 3.5.4-34

Summary of New Road Erosion Risks and Risks of
Sediment Delivery to any Stream and ESA Stream Closest to Proposed TARs and PARs in Range of Oregon Coast Coho

b/ Rainfall Factor and Geologic Erosion Factor from table 3.5.4-32.
c/ Road Delivery Factor from table 3.5.4-33.

EARs. A similar analysis was conducted for EARs that could potentially be utilized during project construction, accessing the construction right-of-way and other project components. The following analysis is limited to segments of EARs that are within 1SPTH from streams within range Oregon Coast coho, including designated critical habitats. EARs include federally-managed roads located on federally-managed lands and privately-owned lands that will be used/authorized during timber removal, construction, and operations to access the construction and operational right-of-way.

There are 79 EAR segments with dirt surfaces and 93 segments with gravel surfaces within 1 SPTH of streams in range of Oregon Coast coho. Of those, only eight segments with dirt surface EARS and 10 with gravel surfaces are within 1 SPTH riparian zones of streams with critical habitat for Oregon Coast coho. Risk estimates for sediment delivery from each of those EARs to 14 streams with critical habitat in range of Oregon Coast coho are summarized in table 3.5.4-35 utilizing the same data sets and factors (Road Slope Factor, Rainfall Factor, Geologic Erosion Factor, and Road Delivery Factor) described above for streams closest to new proposed TARs and PARs. In addition, the Road Surface Factor (1 for dirt, 0.5 for gravel) is included in a Five Factor Product is assumed to represent a level of risk for erosion from each road's surface and has been ranked as Low (product <10), Moderate (product from 10 to <100), and High (product >100) in table 3.5.4-35.

The largest five factor product in table 3.5.4-35 is 605 for the EAR associated with Wallanch Slough due to its dirt surface, high Rainfall Factor, high Geologic Erosion Factor, and direct delivery of sediment assumed since the road crosses Wallanch Slough, apparently over a structure downstream from the pipeline crossing. EARs crossing Laxstrom Gulch, also in the Coos Bay Frontal-Pacific Ocean Watershed, Steele Creek in the North Fork Coquille River Watershed, and South Fork Elk Creek in the East Fork Coquille Watershed pose high risks for sediment delivery to those streams with critical habitat for Oregon Coast coho.

TABLE 3.5.4-35

Summary of New Road Erosion Risks and Risks of Sediment Delivery to
Streams with Coho Critical Habitat by Existing Dirt and Gravel Surfaced Roads within 1 SPTH in Range of Oregon Coast Coho

Watershed and Critical Habitat with EAR	Number of EARs	Road Surface	Total Road Length (miles)	Road Surface Factor a/	Road Slope Factor b/	Rainfall Factor c/	Geologic Erosion Factor d/	Road Delivery Factor e/	Five Factor Product	Risk of Sediment Delivery to Critical Habitat

Saint John Creek	2	Gravel	0.34	0.5	1.0	2.9	1	35	50	Moderate

a/ Road Surface Factors: 0.5 for gravel, 1.0 for dirt. See Table A-3, Appendix A, Dube et al. 2004
b/ Road Slope Factors: 0.2 for gradients of <5%; 1.0 for gradients of 5-10%; 2.5 for gradients >10%. See Table A-6, Appendix A, Dube et al. 2004
c/ Rainfall Factor derived from the average annual rainfall at the closest NWS station, computed using Equation 7, Appendix A, Dube et al. 2004.

d/ Geologic Erosion Factor surmised from Figure A-1 and Table A-1 in Appendix A, Dube et al. 2004 based on Dominant Lithology evaluated from Oregon Department of Geology and Mineral Industries, Oregon Geologic Data Compilation 6. Available from http://www.oregongeology.org/sub/ogdc/index.htm.
e/ Road Delivery Factor: Distance from stream, >200 feet = 0, 100 to 200 feet = 10, <100 feet = 35, and direct delivery = 100. See Table A-10, Appendix A, Dube et al. 2004.

TEWAs. Construction will primarily use a 95-foot wide construction right-of-way corridor and associated TEWAs. However, in specified areas such as wetlands, sensitive visual areas and in residential areas the construction right-of-way will be reduced to 75 feet wide to minimize disturbance. In most cases, except where topographical constraints occur, TEWAs have been located at least 50 feet away from wetland boundaries to minimize impacts to wetland buffers and riparian areas. Where TEWAs are located closer than 50 feet from a waterbody and the adjacent upland does not support cultivated or rotated cropland or other disturbed land, a modification from FERC's Wetland and Waterbody Procedures (Section V.B.2.a. & b.) has been requested.

Distances of TEWAs to Waterbodies within 1 SPTH of designated critical habitat for Oregon Coast coho were measured using GIS and digitized waterbody streambanks and TEWA polygons. Consequently, distances could change once boundaries of TEWAs are surveyed on the ground. From these estimates, there are 26 waterbodies with a total of 77 TEWAs within 1 SPTH of critical habitat for Oregon Coast coho, totaling 31.98 acres. Of those, 37 TEWAs are within 50 feet of the designated critical habitat (summarized from table 3.5.4-36).

Risk estimates for sediment delivery from each of TEWAs similar to that described above for TARs, PARs, and EARs were not conducted since the procedures in WARSEM modeling did not appear appropriate for application with TEWAs except for the road delivery factor (distance from a TEWA to a stream. All but three TEWAs within 1 SPTH of waterbodies with designated critical habitat for Oregon Coast coho are closer than 200 feet to streams, 15 TEWAs within 1 SPTH of waterbodies with designated critical habitat are < 200 feet but >100 feet to streams, and 75 TEWAs within 1 SPTH of waterbodies with designated critical habitat are <100 feet from the streams; 11 of those TEWAs appear to overlap with the waterbodies and consequently provide direct delivery of sediment. TEWAs, within each of those distance categories represent various levels of risks for sediment delivery to designated critical habitats; the TEWAs that overlap waterbodies have the highest risks (11 in range of Oregon Coast coho) of waterbodies with designated critical habitat for erosion and sediment delivery followed by other TEWAs that <50 feet but don't overlap critical habitat (66 in range of Oregon Coast coho) based on the sediment delivery distance categories in WARSEM (Table A-10, Appendix A, Dube et al. 2004).

		TEWA 145.70-N	65	0.28

Erosion of new road surfaces, existing road surfaces, and exposed surfaces of TEWAs within 1 SPTH have the potential for delivery to streams and could lead to adverse effects on fish and fresh water benthic invertebrates similar to those described above. As discussed in Section 2.3 of PCGP's Transportation Management Plan (see POD), PCGP will perform road surfacing structural capacity assessments and place additional road surfacing (aggregate or bituminous as appropriate) as needed for the planned use to minimize the potential for both road-related and off-road resource damage. In WARSEM modeling, the Road Tread Surfacing Factor is 1 for roads with native materials surface but is 0.2 for a gravel (aggregate) surface and 0.03 for an asphalt (bituminous) surface. Application of surfacing materials to any of the new TARs and PARs in table 3.5.4-34 with low to high risks of sediment delivery to streams would decrease levels of erosion and quantities of sediment delivered. Surfaces of all new PARs would be graveled thereby decreasing their erosion potential. Further, PARs and TARs would meet land-managing agencies' engineering design and road management standards consistent with the intended use of the road and all applicable agency BMPs; all applicable agency BMPs for erosion control will be implemented. In addition, PCGP will install appropriate erosion and sediment control BMPs along the access roads as determined necessary by PCGP's EI in cooperation with applicable agency officials. All land-managing agency roads are subject to short-term traffic restrictions and/or closures due to seasonal or unusual weather conditions, user safety or when necessary to prevent facility or resource damage.

PCGP's ECRP also identifies mitigation measures that may be required to minimize potential impacts to existing culverts prior to access road use, to allow safe construction equipment travel and prevent damage to the culverts. PCGP has completed an assessment to identify where proposed road improvements or where new permanent or temporary access roads would cross waterbodies and culvert installations would be required. The assessment used PCGP's wetland survey data where access was available. Where access was not available, the assessment used FWS' National Wetland Inventory (NWI) data[9], USGS National Hydrography Dataset (NHD) data[10], ODF statewide streams data[11], LiDAR data, and aerial photography to interpret waterbody crossings. Identified waterbody crossings were also correlated with PCGP's preliminary access road improvement plans that were completed to evaluate improvements necessary to accommodate trucks hauling pipe (Dyer Partnership 2015). The access road improvement plans (Dyer Partnership 2015) were based on field investigations and identified locations where new culverts or culvert extensions would be necessary.

The new culverts needed to cross waterbodies are located on small intermittent headwater streams where there is no fish presence. The measures outlined in PCGP's Culvert Crossing Best Management Practices (see attachment F to the ECRP in appendix F of the POD) and appropriate erosion control and revegetation measures outlined in the ECRP would be implemented during any road improvement activities. As indicated in the Culvert Crossing BMP, prior to construction, existing culverts will be investigated along all private roads and federally authorized roads (i.e., BLM and Forest Service) identified for access to the construction right-of-way. These investigations would occur on access roads where PCGP is authorized to be and/or where PCGP has negotiated an access use agreement or easement. The investigation will determine the condition and integrity of existing culverts and identify any location that may require mitigative measures to ensure construction activities do not damage or impair the existing function of the culverts. Mitigative measures may be required prior to access road use to allow safe construction equipment travel and prevent damage to the culverts. In select locations, replacement and/or modification of a culvert may be necessary. As noted above, PCGP has completed an assessment to identify where proposed road improvements would cross waterbodies and culvert installations would be required. The new culverts identified are located on small intermittent headwater streams where there is no fish presence.

The ECRP also describes the application of sediment barriers, temporary slope breakers, mulch, dust control, and permanent erosion control measures that will further minimize sediment discharges from a site after construction is complete. In forested areas, during timber clearing/right-of-way grading operations slash-filter windrows may be constructed on the downhill edge of the construction right-of-way and TEWAs, as directed by the EI. Slash-filter windrows will be constructed of logging slash, including cull logs, tree tops, limbs, and branches laid parallel to the right-of-way to effectively filter sediment, reduce runoff velocities, and prevent stream sedimentation. Sediment barriers would generally be placed as follows:

[9] https://www.fws.gov/wetlands/nwi/overview.html
[10] https://nhd.usgs.gov/data.html
[11] http://www.oregon.gov/ODF/AboutODF/Pages/MapsData.aspx

- at the base of slopes adjacent to road, wetland and waterbody crossings where sediment could flow from the construction right-of-way onto the road surface or into the wetland or waterbody;adjacent to wetland and waterbody crossings, as necessary,
- to prevent sediment flow in the wetland consistent with the requirements of FERC's Wetland and Waterbody Procedures; and
- on the down slope side of the right-of-way where it traverses steep side slopes.

The EI will inspect temporary erosion control structures at least on a daily basis in areas of active construction and equipment operation. In areas where active construction and equipment operation are not occurring, inspections will be made at least weekly. All structures will be inspected by the EI within 24 hours of 0.5 inch or greater of rainfall. The EI will be responsible for ensuring that ineffective temporary erosion control measures are repaired as soon as possible but no more than 24 hours after discovery, unless prohibited by exigent circumstances in which case repair will be effectuated as soon as possible. Whenever possible, the EI will inspect erosion control measures in advance of predicted storm events and take preventative measures to minimize the potential for off right-of-way sedimentation.

Temporary sediment barriers will be maintained in place until permanent revegetation measures are determined successful or until the upland areas adjacent to wetlands, waterbodies or roads are stabilized. The structures will be removed once the area has been successfully restored.

Mulch (certified weed free) will be applied if construction and restoration activities are interrupted for extended periods, such as when seeding cannot be completed due to seeding period restrictions. In these areas mulch will be applied uniformly over the area to cover the ground surface at a rate of two tons/acre of straw or hay or its equivalent. In addition, the mulch application rate will also be increased to 3 tons/acre on all slopes within 100 feet of waterbodies and wetlands. The mulch will consist of certified weed-free straw or wood fiber hydromulch. On federal lands, in the event that construction activities are extended beyond the dry season (i.e., May 1 to October 31), soil disturbance in excess of 0.5 acre will have effective ground cover provided or other effective BMPs will be utilized as discussed in this ECRP to prevent sedimentation beyond the approved construction right-of-way and associated TEWAs or into wetlands and waterbodies.

These provisions from the Transportation Management Plan and ECRP are consistent with BMPs identified in Appendix C to Dube et al. (2004) and will ensure that potential sediment delivery from the PARs and TARs is eliminated or minimized resulting in minimal effects to fish and freshwater benthic invertebrates.

Runoff from Facility Surfaces

There are 25 contractor and pipe storage yards, rock source and disposal sites, six new temporary access roads, four new permanent access roads, and nine aboveground facilities within the range of Oregon Coast coho. Five of the yards (North Spit Dock, Weyerhaeuser Cove Pipe Yard, Menasha, K-2, and Brunell) border on Coos Bay and another (Millington 1) borders Isthmus Slough, all designated critical habitat for coho. Several other proposed yards border or are close (<100 feet) to waterbodies inhabited by Oregon Coast coho. They include the Coquille Yard on the Coquille River and the Roth Yard on the South Umpqua River. None of the rock source and disposal sites are near waterbodies inhabited by coho although one new PAR is close to Boone

Creek and one TAR is near Middle Creek in the North Fork Coquille River watershed. Only one aboveground facility, a mainline block valve at Boone Creek Road (Coos Bay-Frontal Pacific Ocean Watershed), is close to a waterbody (Boone Creek) with critical habitat for Oregon Coast coho. The Jordan Cove Meter Station at MP 0.00 is within 440 feet of Jordan Cove.

Stored materials at the yards may include: construction mats, fencing materials, fuel and lubricants, stormwater control materials (straw bales, erosion control fabric, silt fence materials, etc.), and other construction materials. The yards would also be used for contractor office trailers and employee parking facilities. Although the yards are previously disturbed industrial sites, there is some unknown level of risk that stored materials and surface runoff could enter Oregon Coast coho critical habitat.

PCGP has consulted with the BLM, the Forest Service, and the NRCS regarding erosion control and revegetation specifications. Other appropriate agencies have been consulted as well. The Oregon Department of Agriculture Noxious Weed Control Program, as well as the BLM and the Forest Service, have been contacted regarding recommendations for the prevention and spread of noxious weeds with those incorporated into the Pipeline project-specific ECRP. Pursuant to FERC's *Procedures* (see section IV.A), PCGP has prepared a SPCCP for the Pipeline, which includes identifying all potential spill hazards at the facility (including oil) and lists the appropriate response actions and contacts for facility and emergency response personnel. All station technicians would be trained for proper handling, storage, disposal, and spill response of hazardous fluids.

Operation and Maintenance Activities

Once the Pipeline is installed, maintenance would include activities such as aerial inspections, gas flow monitoring, visual inspection of surrounding vegetation for signs of leaks, and integrity management, which includes smart pigging to investigate the interior surface of the pipe for any signs of stress cracking, pitting, and other anomalies (see the ECRP in appendix F). All of the proposed maintenance activities would be outlined in the Operations and Maintenance Plan that would be prepared according to operating regulations in DOT 49 CFR Subpart L, Part 192 and would be completed prior to going in-service. These general maintenance activities would require only surface activities and usage of the existing right-of-way, such as insertion of the pig at one of the pig launching facilities.

Potential estuarine or stream channel disturbance would occur if an integrity issue with the pipeline was found. If this were to occur, the pipeline would need to be unearthed within the right-of-way and repair work done in-water. Within stream sites, repair work could require isolated flow from the section of pipe that is to be exposed. Typically, repairs would be made to the pipe within the right-of-way (within the trench) or, depending on the site-specific conditions and nature of the repair needed, a reroute around the affected section may be considered. Impacts would be similar to those discussed above for initial installation except on a much smaller scale, because they would only involve one crossing compared to many streams. However, should repairs be needed out of the standard stream crossing window (i.e., during periods of fish spawning or egg incubation) there would be additional adverse effects to key fish resources at the specific site. The actions would include all relevant BMPs and mitigation, dependent upon site conditions and land ownership. Any future repairs would require additional permit approval from appropriate state and federal agencies that would determine the acceptable parameters of these actions. Such pipeline integrity-based, in-water projects are very infrequent.

Vegetation maintenance would be limited adjacent to waterbodies to allow a riparian strip to permanently revegetate with native plant species across the entire right-of-way. To facilitate periodic pipeline corrosion/leak surveys, a corridor centered on the pipeline and up to 30 feet wide would be maintained in an herbaceous state, with shrubs outside of this 30-foot corridor. In addition, trees that are located within 15 feet of the pipeline may be cut and removed from the right-of-way. No vegetation or tree limitations would occur beyond the 30-foot-wide corridor in riparian areas (i.e., up to 100 feet of streams on federal lands, and 25 feet non-federal lands).

Herbicide Application

Herbicides have the potential to cause toxic effects to different salmonid life stages and to other aquatic species, causing direct impacts, if used improperly. When herbicides are properly used according to label restrictions and BMPs to control noxious weeds, there is little to no chance of causing injury or mortality to fish or other aquatic organisms.

PCGP would not use herbicides for routine vegetation maintenance. However, following construction, PCGP would implement its IPM (see appendix N to PCGP's POD), which addresses control of noxious weeds and invasive plants across the Pipeline project which would include the selective use of herbicides where necessary to control noxious weeds by limited application from the ground, where allowed by landowners. The plan was developed in consultation with the ODA, BLM, and Forest Service.

The BMPs would minimize the potential spread of invasive species and minimize the potential adverse effects of control treatments. Herbicides would not be applied by aerial or broadcast spraying. Noxious weeds would be removed only by manual methods in the riparian zone defined as one site potential tree height and within Riparian Reserves that are defined as being greater than 150 feet in most areas along the route. PCGP would not directly spray, or otherwise apply, herbicides in waterbodies or in riparian zones. The risk of drift would be avoided by selectively applying herbicides from the ground.

Where weed control is necessary along the construction right-of-way, PCGP's first priority would be to employ hand and mechanical methods (pulling, mowing, biological, disking, etc.) applicable to the species to prevent the spread of potential weed infestations, where feasible. To determine if an herbicide is to be used over other control methods, PCGP would base the decision on weed characteristics and integrated weed management principles (Forest Service 2005). If herbicides are used to control noxious weed infestations, they would be used when they are the most appropriate treatment method. Spot treatments and the use of selective herbicides would be utilized to minimize impact to native or non-target species. Permits or approvals for the use of herbicides and adjuvants on federal lands would be obtained prior to use/treatment, as detailed in the IPM (see appendix N to the POD, available upon request). Considering the potential for limited use of herbicides along the route, and precautions that would be in place to prevent entry into waters, meaningful negative effects to Oregon Coast coho salmon from herbicides would be unlikely to occur.

Cumulative Effects

Cumulative effects in the marine analysis area were presented in the green sturgeon section (3.5.1.3) and would be similar for Oregon Coast ESU coho salmon. These effects include increased boat traffic in the marine analysis area, and the associated potential for increases in noise and fuel and oil spills. The increase in carrier traffic would be slight, as noted in section 3.5.1.3. The slight increase would result in a greater risk of noise impacts on Oregon Coast ESU coho salmon; however, because Project effects are expected to be minor, cumulative effects in the marine analysis area are expected to be insignificant. It appears that the background rate of spills (oil, diesel fuel) off the Oregon coast (incidence of spills in proportion to total carrier operation) by fishing carriers, recreation carriers, and other carrier types is generally low. Based on existing information, future rates of offshore releases are also expected to be low, and therefore the potential for Oregon Coast ESU coho salmon to be affected by oil and other pollutants is not expected to increase above existing levels.

Cumulative effects within the estuarine analysis area were also addressed in the green sturgeon section (section 3.5.1.3), and would be similar for Oregon Coast ESU coho salmon. As noted in this section, overall water quality in the estuary is likely to improve over time because of state and federal regulations. There is likely to be more development in the bay including marina activity, but there are no definite plans for this to occur, so these are not considered “reasonably certain” to occur and are not considered in this cumulative effects section. Therefore, no cumulative effects would occur in the estuarine analysis area to Oregon Coast ESU coho salmon associated with the proposed action and reasonably foreseeable non-federal actions.

Cumulative effects to Oregon Coast coho salmon in the riverine analysis area would be generated by timber harvesting on non-federal lands because there is no federal nexus requiring ESA consultations. Areas of LSOG forest have been monitored as a component of the NWFP. In Oregon, LSOG was evaluated in 1996 (Moeur et al. 2005), in 2006 (Moeur et al. 2011), and in 2013 (Davis et al. 2015). Differences in areas of LSOG forests were described in the four physiographic provinces that coincide with the Pipeline project; from 1993, to 2012 there was an overall net loss of LSOG on non-federal lands within the Coast Range, Klamath, and Western Cascades and Eastern Cascades provinces (see Table 7 in Davis et al. 2015).

During that period, however, areas of LSOG on non-federal lands increased by 6 percent in the Coos Bay Frontal-Pacific Ocean watershed and increased by 30 percent in the East Fork Coquille watershed but decreased by 27 percent and 23 percent within the North Fork Coquille and Middle Fork Coquille watersheds, respectively. In the South Umpqua Subbasin, LSOG decreased slightly in the Olalla Creek-Lookingglass Creek watershed (by 3.2 percent), in the Myrtle Creek watershend (by 0.4 percent), in the Days Creek-South Umpqua River watershed (by 4.5 percent) and decreased substantially in the Upper Cow Creek watershed by 81 percent between 1993 and 2012. Alternatively, LSOG increased in the Clark Branch-South Umpqua River watershed by 23 percent from 1993 to 2012. These changes in areas of LSOG from 1993 to 2012 are clearly evident in figure 3.5.4-7 and figure 3.5.4-8 and, with two exceptions, are similar to trends in other areas under the NWFP. For example, LSOG forest decreased by 26.8 percent between 1993 and 2012 in the Oregon Coast Range physiographic province, decreased by 22.3 percent in the Oregon Western Cascades, decreased by 10.1 percent in the Klamath, and decreased by 14.1 percent in the Oregon Eastern Cascades provinces (Table 7 in Davis et al. 2015). Declines in LSOG were as dramatic or more pronounced on non-federal lands in the physiographic provinces during that same period from 1993 to 2012 (Table 9 in Davis et al. 2015).

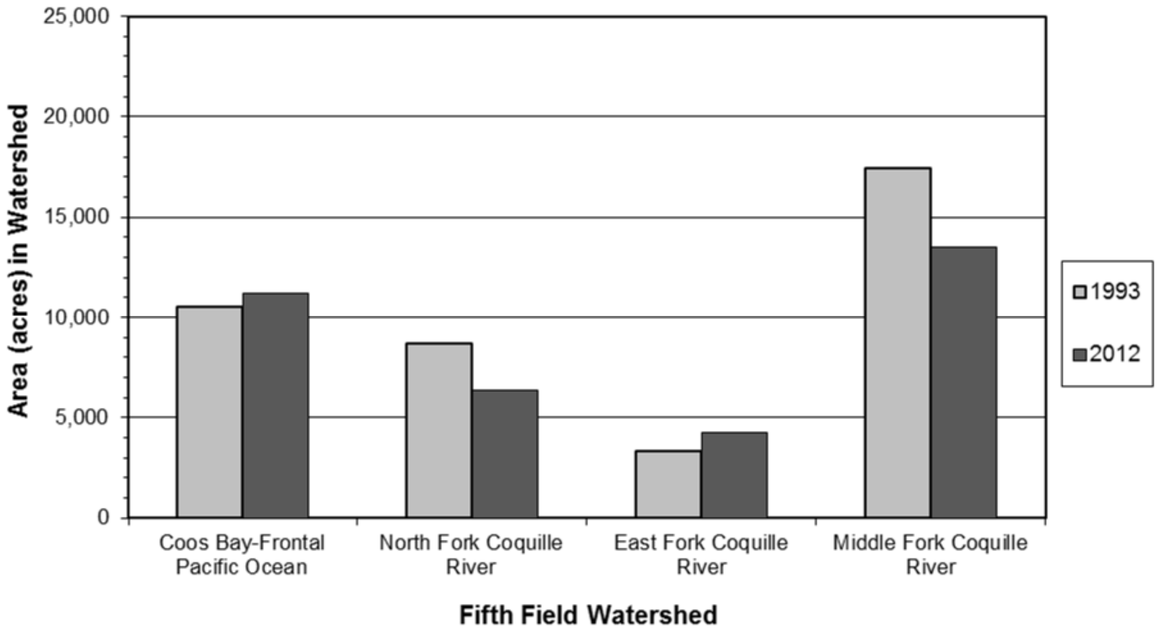

Figure 3.5.4-7 Total Areas (acres) of Late Successional–Old-Growth Forests on Non-Federal Lands in 1993 and 2012 within Four Fifth-Field Watersheds (Coos and Coquille Subbasins) within Range of Oregon Coast Coho Salmon that would be Crossed by the Pipeline Project. (Data from NWFP Interagency Regional Monitoring Program 2017)

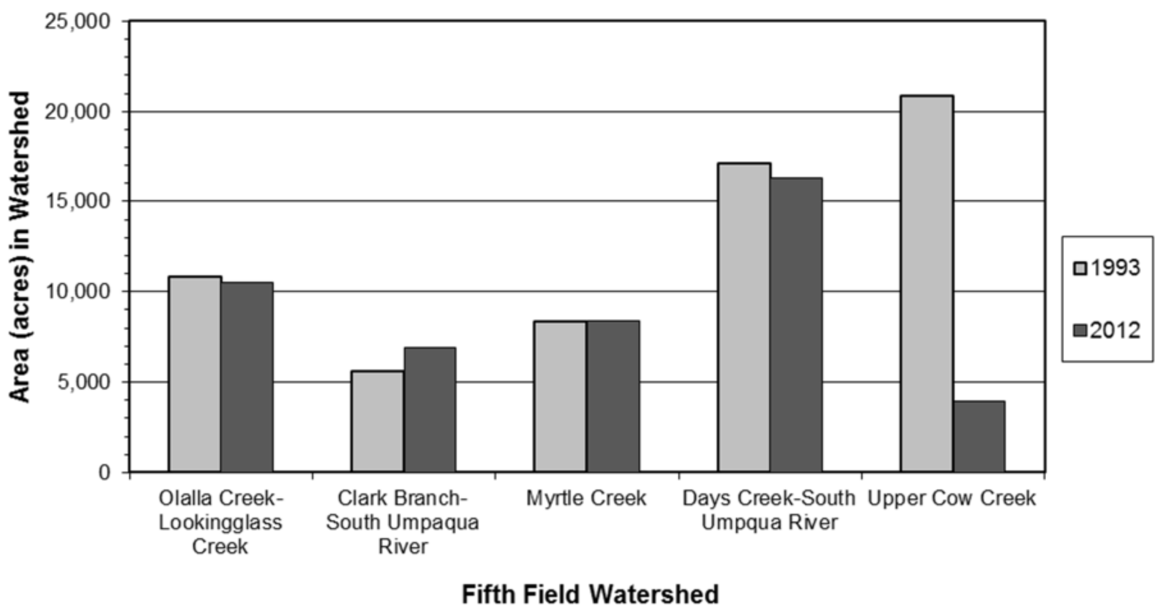

Figure 3.5.4-8 Total Areas (acres) of Late Successional-Old Growth Forests on Non-Federal Lands in 1993 and 2012 within Five Fifth-Field Watersheds (South Umpqua Subbasin) within Range of Oregon Coast Coho Salmon that Would Be Crossed by the Pipeline Project. (Data from NWFP Interagency Regional Monitoring Program 2017)

Based on the past trend there would be less LSOG on non-federal lands in the foreseeable future in all but three of the watersheds affected by the Pipeline project that are within range of coho salmon in the Oregon Coast ESU. Increased LSOG within riparian zones of some watersheds may be possible. Removal of additional LSOG within riparian zones on non-federal land would be more of a reasonably foreseeable cumulative impact. The amount of LSOG on non-federal land through 2020 would be expected to change at the same rate (acres per year) as the amounts that have changed (increased or decreased) between 1993 and 2012. Changes in area of LSOG within the nine fifth field watersheds by the same rate of change observed between 1993 and 2012 were used to predict areas of LSOG in 2020 which, depending on the watershed, are expected to decrease or increase within the nine watersheds crossed within range of Oregon Coast coho (see table 3.5.4-37).

TABLE 3.5.4-37

Estimates for Areas of Late Successional-Old Growth Forest in 2020 on Non-Federal Lands in Fifth-Field Watersheds in Range of Oregon Coast Coho Crossed by the Pipeline Project

Subbasins and Fifth-Field Watersheds	Area (acres) of LSOG on Non-Federal Land			Proportional Change in LSOG per year since 1993	Estimated Area (acres) of LSOG in 2020
	1993 a/	2012 b/	Change in Area from 1993 to 2012		
Coos Subbasin					
Coos Bay-Frontal Pacific Ocean	10,556	11,243	687	0.003	11,532
Coquille Subbasin					
North Fork Coquille River	8,662	6,344	-2,318	-0.014	5,368
East Fork Coquille River	3,303	4,280	977	0.016	4,692
Middle Fork Coquille River	17,408	13,494	-3,914	-0.012	11,846
South Umpqua Subbasin					
Olalla Creek-Lookingglass Creek	10,822	10,479	-343	-0.002	10,334

a/ Data from Regional Ecosystem Office 2017 and Moeur et al. 2005
b/ Data from NWFP Interagency Regional Monitoring Program 2017 and Davis et al. 2015

Amounts of LSOG within the Pipeline project area that would be affected by construction and amounts of LSOG that would be affected within riparian zones (e.g., see table 3.5.4-30a) have been determined. The areas (acres) of all LSOG on non-federal lands within riparian zones 1 SPTH wide are provided in table 3.5.4-30a for each watershed. The data were derived by buffering all streams within each watershed (data from National Hydrography Dataset, USGS 2016) by the 1 SPTH riparian zone widths in table 3.5.4-40 in combination with old growth, 80 years and older spatial data in 2012 (NWFP Interagency Regional Monitoring Program 2017 and Davis et al. 2015) and landownership. The amounts of LSOG forest within non-federal lands in riparian zones that would be removed during Pipeline construction is provided above in table 3.5.4-30a and included in table 3.5.4-38. The Pipeline project would affect between 0 and 0.51 percent of the amount of LSOG (estimated for 2017) on non-federal lands in riparian zones for all streams in each fifth field watershed. With the estimates for areas of LSOG present in 2020, based on proportional changes in areas observed between 1993 and 2012 (table 3.5.4-31), an estimate for area of LSOG on non-federal lands in riparian zones for all streams in each fifth field watershed in 2020 is included in table 3.5.4-38. With the overall change in LSOG expected between 2017 and 2020, the relative effects of Pipeline construction on available riparian LSOG would be expected to remain about the same as current estimates of effects on non-federal lands in the foreseeable future.

Critical Habitat

The Coos Bay estuary and 25 freshwater streams known to support coho within table 3.5.4-1 are designated critical habitat for Oregon Coast coho salmon. Critical habitat is designated to include all river reaches accessible to listed coho within the range of the Oregon Coast ESU. Critical habitat consists of the water, substrate, and adjacent riparian zone of estuarine and riverine reaches in hydrologic units and counties identified in NMFS (1999b)..

Similar to critical habitat designated for coho salmon in the SONCC ESU, critical habitat included stream channels laterally to the ordinary high water mark (OHWM) (or bankfull elevation or bankfull width). NMFS also defined critical habitat in estuarine and nearshore marine zones as areas contiguous with the shoreline from the extreme high water mark out to a depth no greater than 30 meters (98 feet) below the mean low water mark (NMFS 2004). The following are PCEs for designated critical habitat for the Oregon Coast coho (NMFS 2008d):

- Freshwater spawning sites with water quantity and quality conditions and substrate supporting spawning, incubation, and larval development.
- Freshwater rearing sites with water quantity and floodplain connectivity to form and maintain physical habitat conditions and support juvenile growth and mobility; water quality and forage supporting juvenile development; and natural cover such as shade, submerged and overhanging large wood, log jams and beaver dams, aquatic vegetation, large rocks and boulders, side channels, and undercut banks.
- Freshwater migration corridors free of obstruction with water quantity and quality conditions and natural cover such as submerged and overhanging large wood, aquatic vegetation, large rocks and boulders, side channels, and undercut banks a) supporting juvenile and adult mobility and survival, b) supporting juvenile use of various of habitats that allow them to avoid high flows, avoid predators, successfully compete, begin the behavioral and physiological changes needed for life in the ocean, and ability to reach the ocean, and c) essential for nonfeeding adults to successfully swim upstream, avoid predators, and reach spawning areas on limited energy stores.
- Estuarine areas free of obstruction with water quality, water quantity, and salinity conditions supporting juvenile and adult physiological transitions between fresh- and saltwater; natural cover such as submerged and overhanging large wood, aquatic vegetation, large rocks and boulders, and side channels; and juvenile and adult forage, including aquatic invertebrates and fishes, supporting growth and maturation.
- Nearshore marine areas free of obstruction with water quality and quantity conditions and forage, including aquatic invertebrates and fishes, supporting growth and maturation; and natural cover such as submerged and overhanging large wood, aquatic vegetation, large rocks and boulders, and side channels.
- Offshore marine areas with water quality conditions and forage, including aquatic invertebrates and fishes, supporting growth and maturation.

Riparian Zone Effects. Similar analyses to those above under Riparian Vegetation Removal and Modification were conducted for effects to riparian zones associated with each waterbody supporting coho critical habitat and waterbodies that are assumed to provided coho in each watershed. Areas of forested and non-forested habitats that would be affected within the riparian zones of each waterbody during construction are provided in table 3.5.4-39a and areas affected during operation are provided in table 3.5.4-39b and summarized in table 3.5.4-39c. The tables also include riparian zone areas affected by landowner, similar to tables 3.5.4-30a and 3.5.4-30b.

a/ Project components considered in calculation of habitat "Removed:" PCGP construction right-of-way, temporary extra work areas, aboveground facilities, and permanent and temporary access roads (PAR, TAR).

b/ Habitat Types within Riparian Zones generally categorized as: Late Successional (Mature) or Old Growth Forest (coniferous, deciduous, mixed ≥80 years old); Mid-Seral Forests (coniferous, deciduous, mixed ≥40 but ≤80 years old); Regenerating Forest (coniferous, deciduous, mixed ≥5 but ≤40 years old); Clearcut Forests; Forested and Nonforested Wetland, Unaltered Nonforested Habitat (grasslands, sagebrush, shrublands), Agriculture, and Altered Habitats (urban, industrial, residential, roads, utility corridors, quarries).

c/ Riparian zone of Stock Slough at MP 15.11BR includes the riparian zone of Laxstrom Gulch which is adjacent to the pipeline but not crossed. Laxstrom Gulch is also designated Critical Habitat.

Effects to water temperature (shade) during construction and operation within the riparian zone of each waterbody assumed to support coho or with coho critical habitat are assumed to be directly related to areas of riparian forest removed during construction (riparian forest within the construction right-of-way, TEWAs, TARs, and PARs) and to areas of riparian forest that would be removed within the 30-foot wide operational easement for the life of the Pipeline. Riparian forest that is not in the operational easement would be restored over time, presumably attaining mid-seral status (40-80 years old) at the end of the 50-year life of the Pipeline. The magnitude of impact to riparian shade associated with each waterbody with critical habitat and assumed to be occupied by coho is directly related to the absolute and relative amounts of riparian forest removed during construction, amounts removed permanently by the operational easement, and amounts of riparian forest that would be restored within affected riparian zones.

Table 3.5.4-39c summarizes tables 3.5.4-39a and 3.5.4-39b. In table 3.5.4-39c below, the greatest absolute impact to LWD recruitment and shade within riparian zones associated with critical habitats for Oregon Coast coho would occur where the pipeline crosses Steinnon Creek, South Fork Elk Creek, Olalla Creek, Saint John Creek, and the South Fork Umpqua River where more than one acre of riparian forest would be removed at each one. Likewise, there would be high absolute impact to several streams that are known to (e.g., Tributary to Cooston Channel) or assumed (six streams) to support coho. In addition to those, relatively large amounts of riparian forest would be affected during construction at Kent Creek, Rice Creek, and North Myrtle Creek but relatively large areas of forest restoration following construction would partially offset the effects of construction. Riparian forest that would be restored would presumably attain mid-seral status (40-80 years old) at the end of the 50-year life of the Pipeline. Absolute and relative impact to forests within riparian zones (with concomitant effects to LWD recruitment and shade) associated with other affected waterbodies with critical habit for Oregon Coast coho would be less severe. The longest-term effects to riparian forest, LWD and shade would occur where late successional-old growth forest would be removed during construction: 0.89 acre at Vogel Creek (Coos Bay Frontal-Pacific Ocean Watershed), 0.81 acre at Middle Creek (North Fork Coquille River Watershed), 0.01 acre at McNabb Creek (Olalla Creek-Lookingglass Creek Watershed), 0.10 acre at North Myrtle Creek (Myrtle Creek Watershed), and 0.54 acre at Saint John Creek (Days Creek-South Umpqua River Watershed).

Effects to LWD during construction and operation within the riparian zone of each waterbody assumed to support coho or with coho critical habitat are assumed to be directly related to areas of riparian forest removed during construction (riparian forest within the construction right-of-way, TEWAs, TARs, and PARs) and to areas of riparian forest that would be removed within the 30-foot wide operational easement for the life of the Pipeline. Riparian forest that is not in the operational easement would be restored over time, presumably attaining mid-seral status (40-80 years old) at the end of the 50-year life of the Pipeline. The magnitude of impact to LWD recruitment associated with each waterbody with critical habitat and assumed to be occupied by coho is directly related to the absolute and relative amounts of riparian forest removed during construction, amounts removed permanently by the operational easement, and amounts of riparian forest that would be restored within affected riparian zones.

The Pipeline project would result in adverse effects to freshwater critical habitat for the Oregon Coast ESU of coho salmon. Most effects would be short-term, but some would be intermediate to long-term. Minor short-term effects would occur from sedimentation during construction actions. Minor intermediate-term effects would occur from a reduction in riparian habitat due to construction and operation. Sediment disturbance at stream crossings would affect food sources for rearing fish in the short-term, and riparian plant removal would reduce LWD supply affecting habitat quality and quantity in the intermediate to long-term over small stream areas (i.e., within the less than 75 to 95-foot stream length cle aring area per crossing).

Designated critical habitat for the Oregon Coast coho does not include unoccupied areas. The lateral extent of critical was defined as the width of the stream channel defined as the ordinary high-water line (NMFS 2008d). Human actions on land outside of the stream channel can modify or degrade physical and biological features of the stream and associated PCE at the site and/or in downstream reaches of designated critical habitat. Each PCE defined for critical habitat could be adversely affected by the proposed action. Those effects have been quantified to the extent possible in the foregoing analyses and summarized below in table 3.5.4-40.

Project effects to freshwater spawning sites would likely occur prior to coho spawning in the year of construction and there would be no effects to spawning, incubation, and larval development by suspended sediment although project-generated sediment could increase gravel embeddeness downstream. Those effects would depend on precipitation and in-stream flow (potential freshets) following construction that would likely flush fines downstream. The project would remove small areas of riparian forest that would provide recruitment of LWD. The Project would temporarily decrease water quality downstream from construction sites by entrainment of sediments and temporarily limit in-stream migration during in-stream construction. In all instances, habitat suitability (HADD, Anderson et al. 1996) would temporarily decrease though not necessarily to levels that would cause moderate habitat degradation (SEV = 7).

The Project could result in short-term adverse effects to estuarine and freshwater critical habitat for the Oregon Coast ESU of coho salmon. Short-term effects to critical habitat within the estuarine analysis area would include effects to food and rearing habitat as a result of dredging the access channel, NRIs and the slip. Dredging in proximity to the Coos Bay shipping channel would decrease water quality and affect cover (aquatic vegetation, eelgrass).

In the riverine analysis area, most effects to critical habitat would be short-term while some would be intermediate to long-term. Minor short-term effects would occur primarily from sedimentation during stream crossings. Minor intermediate-term effects would occur from a reduction in riparian habitat that would affect freshwater rearing habitat due to construction and operation. Sediment disturbance at stream crossing would affect food sources for rearing fish in the short-term, and riparian plant removal would reduce LWD supply affecting habitat quality and quantity in the intermediate to long-term over small stream areas (i.e., within the less than 75- to 95-foot stream length clearing area per crossing).

3.5.4.4 Conservation Measures

Appendices N and O of this BA include a complete list of conservation measures proposed by JCEP and PCGP. Measures that are applicable to Oregon Coast ESU coho are summarized here. JCEP would undertake a number of measures designed to mitigate the potential construction and operation impacts on fisheries and aquatic resources as described in the above sections. Construction phase mitigation would include measures to avoid or minimize the potential impacts from construction of the slip as well as from activities in upland areas associated with construction of the LNG Terminal and related facilities. In addition, restoration activities at the Kentuck Project and at the Eelgrass Mitigation site would offset the permanent loss of intertidal, subtidal, salt marsh, and eelgrass habitat resulting from construction of the slip and access channel. During operation of the LNG Terminal, mitigation measures would be incorporated at the LNG Terminal site to minimize the potential for discharge of pollutants or hazardous materials into the bay. Additional mitigation procedures would be implemented to ensure that LNG carriers would not adversely impact marine organisms either through direct mortality or through the introduction of exotic marine species.

Conservation measures proposed by JCEP to minimize impacts from LNG carrier transit, LNG Terminal and facility construction and operations to fisheries in the marine and estuarine analysis area are compiled in tables 1, 2A, and 2B in appendix N (see discussion in section 3.3.1). JCEP has also proposed measures to rectify, repair, rehabilitate, and otherwise reduce impact to from actions noted once construction is complete; these measures are compiled in tables 3A and 3B in appendix N.

Without repeating the components proposed by the JCEP that are in appendix N, they include measures related to:

- Timing of Dredging Activities – to minimize potential impacts to juvenile salmonids and other fish/invertebrate species through the avoidance of vulnerable life stages and peak migration periods;
- Berm Construction Containment – conduct most slip dredging behind soil berm to limit sedimentation in marine waters and no Coos Bay water disposal activities;
- Dredging and Disposal Activities – use of dredge equipment and techniques to minimize the potential for turbidity and contaminant releases to the water column;
- Use of Upland Disposal of Dredge Materials – includes removal of dredged spoils by barge and containment of elutriate water;
- Control of Turbidity and Contaminants – includes monitoring, corrective actions, upland and water containment, and dredging technique;
- Stormwater Management – initial run off of all storms of a two –year return period to be contained and infiltrated, the remainder will flow to the slip;
- Timing of In-water Temporary Construction Components and Terminal Construction Components – to minimize potential impacts to juvenile salmonids and other fish/invertebrate species through the avoidance of vulnerable life stages and peak migration periods;
- Control of Acoustic Disturbance – includes impact hammer work (pilings and sheet piles) behind berm outside of marine waters and monitoring plan;
- Riprap Installation – using smallest size practical;
- Lighting – direct light to shore and at lowest levels possible design; and
- Spill Prevention and Control – includes development and implementation of an SPCCP.

Conservation measures have also been proposed by PCGP to minimize construction and operation impact in the riverine analysis area and estuarine analysis area crossed by the Pipeline. Those measures are compiled in tables 1 and 2C in appendix N and are summarized below. PCGP has also proposed measures to rectify, repair, rehabilitate, and otherwise reduce impact to waterbodies and riparian zones once construction of the Pipeline is complete. Those measures have been compiled in table 3C in appendix N. Details of some of the major conservation measures proposed by PCGP are summarized below.

Erosion Control

Many of the conservation measures in table 3C in appendix N focus on erosion control to prevent sediment from entering surface waters. Temporary erosion controls would be installed immediately after vegetation clearing and grading and would be properly maintained throughout construction and reinstalled as necessary until replaced by permanent erosion controls or restoration is complete. At a minimum, the following temporary erosion control structures would be installed: temporary slope breakers, sediment barriers, mulch, and erosion control fabric. PCGP would install permanent slope breakers consistent with the requirements of the FERC's Plan.

Part of long-term erosion control would include a final cleanup including final grading and installation of permanent erosion control structures. Final cleanup of an area would generally occur within 10 days after backfilling the trench and not be delayed beyond the end of the next recommended seeding season. During final cleanup, PCGP would remove all construction debris and grade disturbed areas to pre-construction grades to the extent practicable. An adequate seedbed would be prepared at the conclusion of cleanup.

Temporary Slope Breakers

PCGP would install temporary slope breakers over the backfilled, recontoured construction right-of-way as specified in the FERC's Plan. The outfall of each temporary slope breaker would be to a stable, well-vegetated area or to an energy-dissipating device at the end of the slope breaker off the construction right-of-way. Slope breakers reduce runoff velocity, thereby intercepting sediment and allowing it to drop out of suspension. They also can effectively divert runoff away from a disturbed site to a stable outlet (Goldman et al. 1986).

Sediment Barriers

PCGP would primarily rely upon silt fence and staked hay or straw bales to confine sediment to the construction right-of-way. These structures would be used adjacent to wetland and waterbody crossings consistent with the requirements of the FERC's *Procedures*. Straw bales and filter fabric (silt fence) can be used together to create a highly effective sediment barrier, a combination that compensates for the limitations of each used in isolation; straw bales provide extra support and the fabric provides greater filtering capability (Goldman et al. 1986).

All straw or hay bales used for sediment barriers would be certified as weed-free. Temporary sediment barriers would be maintained in-place until permanent revegetation measures are successful or until the upland areas adjacent to wetlands, waterbodies or roads are stabilized. The structures would be removed once vegetation in the area has been successfully restored.

Erosion Control Fabric

PCGP would install erosion control fabric (such as jute or excelsior) on waterbody banks at the time of recontouring. The fabric would be anchored using staples or other appropriate devices. Although there are no measures specific to pipeline construction, data related to cut-and-fill slopes treated during construction of forest roads indicate varying effectiveness of different types of stabilization measures designed to control surface erosion (EPA 2001). On fill slopes, combining straw mulch and netting decreased erosion by 99 percent. Excelsior mulch alone decreased erosion by 92 percent on fill slopes. On cut slopes, straw mulch by itself decreased erosion in a range from 32 to 97 percent (EPA 2001). Applications of mulches and/or fabric are effective measures promoting slope stabilization until vegetation can successfully be reestablished. These measures also promote plant growth (EPA 2001).

Fish Salvage Plan

All waterbodies that would be crossed by dry open cut construction would be done prior to adult coho salmon upstream migration, within ODFW in-stream construction windows. A *Fish Salvage Plan* has been provided in appendix T. The plan has been developed to minimize adverse effects to listed salmonids (SONCC coho salmon, Oregon Coast coho salmon), non-listed salmonids (Chinook salmon, steelhead, and cutthroat trout) and listed catostomids (Lost River sucker, shortnose sucker). The portions of the plan relevant to salvaging salmonids were adapted from the protocol developed by WSDOT (2012). The protocol specifies procedures to 1) isolate the work area; 2) remove fish and dewater the work area; 3) handle, hold, and release fish; 4) document fish that have been captured, handled, held, and released; and 5) notify NMFS and FWS. Only trained professionals would conduct electroshocking and fish removal.

Revegetation

As required by the FERC's *Plan*, PCGP has identified procedures for the preparation and planting of live stakes or sprigs and for the planting bare root tree seedlings. Those procedures are included in appendix R. Within the range of Oregon Coast coho salmon, construction of the Pipeline would remove 112.96 acres of riparian forested habitats of which 16.86 acres are late-successional (mature) old-growth, 45.82 acres are mid-seral forests, and 0.07 acre is forested wetlands (see table 3.5.4-30a).

Existing forested riparian zones in which forest would be removed during construction would be re-planted with conifers to within 15 feet of each side of the centerline. Permanent effects—persisting longer than the assumed 50-year life of the Pipeline—would occur by removing 16.86 acres of late-successional (mature) old-growth riparian forest. Even though the riparian zone would be replanted, the newly planted trees would not attain late-successional or old-growth status within 50 years. Permanent effects would also last along the 30-foot wide maintenance corridor centered on the Pipeline. Those effects to former late-successional (mature) old-growth riparian forest, mid-seral riparian forest and other existing riparian vegetation are included in table 3.5.4-30b. Due to the maintenance access route in the right-of-way that would not be allowed to grow trees for the life of the Pipeline project, replanting conifers within each affected forested riparian zone would leave an estimated 28.27 acres of non-forested vegetation within former forested riparian zones over the long-term or permanently (see table 3.5.4-30b).

OHV Barriers

Limiting OHV vehicles access would reduce potential increased sedimentation to streams and human access to sensitive fish areas. In accordance with the FERC's *Plan*, the applicant must offer to install and maintain measures to control unauthorized vehicle access to the right-of-way to each landowner or manager of forested lands to install and maintain measures to control unauthorized vehicle access to the right-of-way and states that such measures may include signs; fences with locking gates; slash and timber barriers, pipe barriers, or a line of boulders across the right of way; and conifers or other appropriate trees or shrubs across the right-of-way. If allowed by the landowner, and if available, slash, stumps and or logs, if available, would be placed on the right-of-way within the riparian zones to discourage OHV crossings of streams and provide carbon and nutrients if allowed by the landowner. If not allowed, PCGP would discuss with the landowner the use of other methods, as noted above. At a minimum the area would be revegetated and re-seeded.

Streambank Stability

The root network of trees adjacent to streambanks is essential to maintaining streambank stability (WDNR 1997). Because root strength decreases significantly at distances beyond one-half the tree crown diameter, trees promoting streambank stability lie within half a tree crown diameter from the streambank. Trees within 25 feet of the streambank are assumed to promote streambank stability (WDNR 1997). Generally, trees that must be removed during construction would be cut at ground level with the roots left in place, except where located within the trenchline. Although roots would decay overtime, streambank stability would be retained by their presence until revegetation is successful.

Streambank Restoration

PCGP's ECRP (see appendix F) describes the measures that would be used to stabilize streambanks crossed by the Pipeline. PCGP would not use riprap to stabilize streambanks. The alignment has been designed at waterbody crossings to be as perpendicular to the axis of the waterbody channel, as engineering and routing constraints allow, minimizing streambank disturbance and avoiding parallel stream alignments or multiple stream crossings. Immediately after installation of a waterbody crossing, the contours of the streambed, shoreline, and streambanks would be restored to preconstruction configurations (i.e., contour/elevations) to restore the physical integrity/condition of these features and to minimize the loss of stream complexity.

PCGP has completed a scour analysis for the Pipeline project that would be used to ensure that appropriate pipeline burial depths and cover design parameters beneath channel streambeds and adjacent floodplains are utilized, so that the effects on natural stream processes would be avoided or minimized. The Pipeline project's scour analysis, which was completed by GeoEngineers, was included in PCGP's 2017 FERC certificate application.

PCGP would install erosion control fabric (such as jute or excelsior) on streambanks at the time of recontouring. The fabric would be anchored using staples or other appropriate devices. The erosion control fabric to be used on streambanks would be designed for the proposed use and would be approved by PCGP's EIs.

Consistent with the FERC's *Procedures* (section V.C.3.), during streambank restoration/recontouring, the streambanks would be returned to their preconstruction contours or to a stable configuration. Streambank revegetation measures, including supplemental riparian planting procedures are also outlined in the ECRP. The shrubs and trees planted at each site would be determined at the time of planting based on the moisture regimes and site-specific conditions at each planting location and landowner requirements.

In-Stream Gravel

Waterbodies supporting fisheries would be backfilled with material removed from the trench with the upper 1 foot of the trench backfilled with clean gravel or native cobbles. PCGP has requested a variance from section V.C.1. of the FERC's *Procedures* in fish-bearing streams that do not have gravel, cobble, or other rock substrates prior to construction. This variance was requested because many of the streams crossed are remote and are located in steep valley or ravine bottoms. Therefore hauling rock to these steams is impractical especially where these streams do not have gravel or cobble substrate characteristics prior to construction. The bottom and banks would be returned to preconstruction contours; banks would be stabilized; and temporary sediment barriers would be installed before returning flow to the waterbody channel.

Large Woody Debris

As discussed in the Direct and Indirect Effects section above in several instances, mitigation would contribute to restoring an aquatic habitat indicator's functional level, such as placement of LWD within and/or adjacent to streams and placing LWD on floodplains, where appropriate, to provide microsites for riparian vegetation and/or vegetation protection during flood events. Placement of LWD in streams and/or on streambanks has been one focal point of recent stream rehabilitation procedures (Slaney and Martin 1997; Cederholm et al. 1997; EPA 2001) as described in the *Large Woody Debris Plan* (see appendix O).

As indicated in table 3.5.4-10a and table 3.5.4-10b, baseline watershed conditions crossed by the Pipeline are lacking in LWD due to historical disturbance and LWD presence is typically below benchmark thresholds to be properly functioning. Because of the overall lack of LWD in the affected watersheds, LWD also provides an appropriate mitigation model for the Pipeline project's potential waterbody crossing impacts that are temporary, short-term, and unavoidable (see appendix O). If approved by landowners, PCGP proposes to install LWD on-site during construction as an appropriate habitat enhancement feature to mitigate for potential pipeline impacts and to benefit watershed conditions. The LWD would also serve to mitigate for potential long-term Pipeline project impacts—impacts lasting for its 50-year life—such as the loss of forested riparian vegetation within the 30-foot operational corridor (see table 3.5.4-30b, above). Even though the riparian zone would be replanted, the planted trees would not attain late-successional or old-growth status within 50 years. Placement of LWD would, in some measure, reduce though not eliminate the impact due to the removal of late-successional (mature) old-growth riparian forest.

For low-gradient streams, Cederholm et al. (1997) suggest using logs with diameters at least 18 inches (less in areas of low velocity) placed by vertical angling into the stream channel. Logs could be used to create a stepped-channel profile with the rootwads and encourage woody debris accumulations in pool margins. For streams with steeper gradients, Cederholm et al. (1997) suggest that logs with smaller diameters might be used if larger logs are unavailable. Near headwaters, LWD is often suspended over the channel so that it can become functional during periods of maximum runoff. Smaller debris may be retained during those periods and help develop pools that would be functional during summer (see Cederholm et al. 1997).

Guidelines for LWD placement, provided by ODF and ODFW (1995), suggest using the following: 1) larger diameter wood pieces because they are more effective at creating pools and complex channels which improve fish populations (see table 3.5.4-41 for minimum diameter LWD per bankfull width); 2) LWD that are at least twice the length of the waterbody bankfull width (1.5 times the bankfull width if the rootwad is attached) to increase the likelihood that the LWD would remain in place; and 3) conifer logs, especially western red cedars if available, because they are more durable. In larger waterbodies, smaller diameter, shorter LWD could be used if bundled and anchored together to provide the same benefits of the longer, larger diameter LWD (ODF and ODFW 1995).

TABLE 3.5.4-41

Minimum Diameter LWD for Placement in Waterbody Based on Bankfull Width

Bankfull Width (feet)	Minimum Diameter LWD (inches)
0 to 10	10
10 to 20	16
20 to 30	18
Over 30	22

Source: ODF and ODFW 1995.

Trees classified as late successional or old growth are assumed to have attained heights equal to the site-potential tree heights that are included above in table 3.5.4-30a as Riparian Zone Widths. Site-potential tree heights range from 225 feet (for example, the Coos Bay-Frontal Pacific Ocean Watershed) to 164 feet (as in the Days Creek-South Umpqua River Watershed). If Douglas-fir trees in the Oregon Cascades grow in height at the rate of 20 inches per year and in diameter by 0.25 inch per year (Cox 2008), a 20-inch-tall seedling planted the year after construction of the Pipeline would be an estimated 85 feet tall and 12 to 13 inches in diameter (assumed dbh) after 50 years. Trees with those dimensions would provide suitable LWD for streams with bankfull widths from zero to 10 feet but not larger streams (see table 3.5.4-41). Even in these streams recruitment of wood may be reduced as the young age of the forest would reduce recruitment from natural mortality as the rate would be less relative to older trees. But recruitment of wood is not solely dependent on natural tree mortally but includes important contributing factors such as bank erosions, disease, fires, slides, and windthrow (Reeves et al. 2003; Martin and Benda 2001; Gregory et al. 2003). LWD contribution would occur from these areas even though natural mortality contribution would be reduced.

The Pipeline would cross 50 perennial streams within the range of Oregon Coast ESU coho salmon. Forty-five of those perennial streams have existing riparian forest ranging from clear – cut forest and regenerating forest to mid-seral stage (approximately 40 to 80 years old) to older late-successional and old-growth; 39.45acres of existing riparian forest would be removed by construction. Five more perennial streams would also be crossed but construction would not affect riparian forest vegetation (see table 3.5.4-42). In addition, the Pipeline would cross 56 intermittent streams, 46 of which support riparian forest, and would affect riparian forest of 52 other intermittent streams, resulting in a total of 113.09 acres of riparian forest being removed. Six additional perennial streams and 25 intermittent streams with no riparian forest would be crossed as well (see table 3.5.4-42).

To offset impact from removal of riparian trees (reducing LWD recruitment potential) and to provide an overall benefit by enhancing stream habitat with no potential for LWD recruitment, PCGP proposes to place LWD at the waterbody flow types identified by watershed in table 3.5.4-42 (see the *Large Woody Debris Plan* in appendix O) based on the following applications:

- four pieces for each perennial stream crossed with riparian forest removed (two pieces in-stream and/or keyed into the streambank, two pieces within riparian zone on the bank);
- two pieces for each intermittent stream and unknown stream crossed with riparian forest removed (one or both LWD pieces placed in-stream, keyed into the bank, or placed on the bank);
- two pieces for each perennial, intermittent, and unknown stream crossed but with no riparian forest removed (one or both LWD pieces paced in-stream keyed into the bank, or placed on the bank); and
- one piece each for a perennial, intermittent, and unknown stream not crossed but adjacent to the construction right-of-way, with or without riparian forest removed (LWD placed on bank).

Because the construction right-of-way at stream crossings would be 75 feet wide, PCGP anticipates only enough space for two pieces of LWD, preferably with rootwads attached, either placed in-stream or with stems keyed into streambanks. Unless site-specific conditions dictate otherwise, the preferable location for each in-stream LWD is downstream from the pipeline to prevent scour of the pipe. LWD would also be placed near or adjacent to streambanks within riparian zones to provide for and/or enhance microsites for riparian vegetation and/or vegetation protection during flood events.

The LWD plan includes placing from one to four pieces of LWD per stream crossed in the stream or on the bank, depending on forest conditions, stream flow, and landowner approval. This number of pieces, if no other LWD were present in the stream reach affected by clearing, would be in the range of what is considered "desirable" by ODFW (Foster et al. 2001) for forested streams. Foster et al. (2001) noted that more than 20 LWD pieces/100 meters of stream length (i.e., 4.6 pieces/75 feet of right-of-way clearing) with more than 3 "key" pieces/100 meters (i.e., 0.7 "key" pieces/75 feet of right-of-way clearing) is considered "desirable" in way.
table 3.5.4-32 to meet habitat needs for specific stream sizes and number of streams crossed.

In all, PCGP proposes 375 pieces of LWD for placement within the nine fifth-field watersheds that coincide with Oregon Coast coho salmon ESU and designated critical habitat. Placement of LWD is subject to approval by each affected landowner. If a landowner rejects the proposed placement of LWD, the number of pieces that would have been applied on-site would be reserved and provided to appropriate watershed councils for their use and placement, preferably elsewhere within the affected fifth-field watershed.

a/ Proposed schedule for applying LWD to different waterbody types, subject to landowner approval:
4 pieces for each perennial stream crossed with riparian forest removed (2 pieces in-stream, 2 pieces within riparian zone on the bank);
2 pieces for each intermittent stream and unknown stream crossed with riparian forest removed (one or both pieces placed in-stream or on bank);
2 pieces for each perennial, intermittent, and unknown stream crossed but with no riparian forest removed (one or both pieces paced in-stream or on bank).
1 piece each for perennial, intermittent, and unknown stream not crossed but adjacent to ROW with or without riparian forest removed (piece placed on bank).

PCGP anticipates that during construction, in some cases, the waterbody size, landowner restrictions, or construction constraints would limit LWD placement according to the proposed LWD schedule provided in table 3.5.4-42. Further, the overall benefit of installation of LWD at some waterbody crossings (i.e., intermittent headwater streams) may not warrant LWD placement. In these situations, PCGP's EI would record the uninstalled LWD as a deficit during construction. After construction is completed, unutilized LWD would be provided to local watershed conservation organizations or agencies for use in local enhancement projects within the affected watersheds. (Also see the discussion on the use of LWD for mitigation in appendix O.)

Stream Crossing Monitoring

PCGP's Stream Crossing Risk Analysis (GeoEngineers 2017d, 2017e, and 2018a) and appendix O.2 to PCGP's Resource Report 2) provides site-specific BMPs to restore streambed and banks for long-term stability and to restore aquatic habitat. This Risk Analysis also provides a stream crossing monitoring plan to ensure long-term success of stream restoration, maintenance of fish passage, and identification of channel erosion, scour or migration that could destabilize the site or expose the pipeline. Streambank revegetation measures are outlined in the ECRP (see appendix F). Appropriate restoration BMPs, outlined in the Site-Specific Stream Crossing Prescriptions for the Perennial Streams on BLM and National Forest lands (North State Resources 2014), would also be incorporated during construction and restoration in consultation with the agency's authorized representative and PCGP's EI or authorized representative. The monitoring plan is described in the section on Streambank Erosion and Streambed Stability, above.

3.5.4.5 Determination of Effects

Species

The Project **may affect** coho salmon in the Oregon Coast ESU because:

- several life stages and activities of coho salmon (upstream adult migration, juvenile fry rearing, and juvenile smolt out-migration) are expected to occur at various locations in the riverine analysis area during construction and operation of the proposed action;
- several life stages and activities of coho salmon (juveniles, adults) are expected to occur within the estuarine analysis area during construction and operation of the proposed action; and
- adult and juvenile coho salmon are expected to occur within the marine analysis area during operation of the proposed action.

While several project actions are not likely to cause adverse effects, those Project components that are **likely to adversely affect** coho salmon in the Oregon Coast ESU include those listed below.

- Short-term increase in noise associated with MOF land-based pile driving and in-water pile driving at various temporary construction activities throughout the bay may cause disturbance and physical injury to Oregon Coast coho if they are in proximity to the noise during construction.

- Some juvenile coho may be subject to localized entrainment by capital dredging associated with the access channel and Navigation Reliability Improvements, which will be further assessed under subsequent regulatory consultations during the project operations phase.
- Local, short-term increases in suspended sediment in Coos Bay from in-water construction, particularly during dredging, may result in behavioral effects on rearing coho salmon juveniles with physiological consequences that may affect growth and surviva.l
- Short-term effects to the benthic community and potential food resources for Oregon Coast coho would result from dredging the proposed access channel and Navigational Reliability Improvements in Coos Bay.
- Even though most juvenile coho would be of sufficient size and swimming ability to avoid the LNG carrier cooling water intake, a limited number could be entrained during spring and summer while they rear in Coos Bay concurrent with carrier loading operations.
- TSS could adversely affect juvenile coho salmon. Exposure of juvenile fry to TSS concentrations during dry open-cut construction (fluming or dam-and-pump) from 2 to 6 hours could potentially exceed SEV5 for an estimated 264 to 615 m or more downstream in some watersheds. Such an effect could cause a minor physiological stress (increased coughing rate and/or increased respiration rate).
- Individual coho salmon may be directly affected by local restoration activities at the Kentuck Project due to short-term construction-related increases in turbidity, in-water work and isolation measures.
- If a failure occurs while dry open-cut construction is underway, there could be possible adverse effects to juvenile coho (SEV of 7 or 8) including moderate habitat degradation and impaired homing by fish or major physiological stress to fish. The most likely effect could include moderate habitat degradation, impaired homing by fish, and moderate to major physiological stress, but in very limited areas may include reduced growth and reduced fish density.
- Construction requiring blasting at 22 streams that are known or assumed to support coho could cause mortality to fish by rupturing swim bladders. Adult and juvenile coho salmon would be removed and/or prevented from being within 50 feet of blasting sites to the maximum extent possible.
- Fish salvage would occur within isolated construction sites, possibly when adult and juvenile coho salmon are present. Coho salmon are considered vulnerable to electrofishing, subject to injury and mortality. Seining, electrofishing, and handling may adversely affect Oregon Coast coho salmon. A worst case estimate of 963 juvenile coho could potentially be salvaged from streams crossed by dry open-cut procedures
- Lack of LWD is a limiting factor in most streams within range of Oregon Coast coho salmon. Removal of mid-seral riparian forest (40 to 80 years old) would have long-term effects to recruitment of LWD and removal of LSOG forest (≥80 years old) would have permanent effects to recruitment of LWD because planted conifers would not attain those age classes within the 50-year life of the Project.

Critical Habitat

The Project **may affect** designated critical habitat for coho salmon in the marine analysis area, within the estuarine analysis area, and within the riverine analysis area for the Oregon Coast ESU because:

- actions associated with construction and operation of the LNG Terminal and access channel and slip would occur within designated critical habitat; and
- the Pipeline crosses designated critical habitat within Coos Bay and riverine waterbodies of the Coos, Coquille, and South Umpqua Subbasins.

Project components are **likely to adversely affect** designated critical habitat for coho salmon in the Oregon Coast ESU because:

- localized, short-term effects to the benthic community and potential food resources for Oregon Coast coho would be result from dredging the proposed access channel and Navigation Reliability Improvements in Coos Bay;
- TSS concentrations generated during dry open-cut construction and if failure of isolation structures occur, would adversely affect freshwater habitats by changing coho habitat preferences (SEV = 3) or causing moderate habitat degradations (SEV = 7 or 8);
- food resources would potentially be affected over the short-term by dry open-cut and diverted open-cut construction methods that would remove substrate and benthos at crossing sites and produce turbidity downstream in all streams likely to support Oregon Coast coho salmon;
- approximately 201 acres of riparian zone habitat associated with waterbodies within range of Oregon Coast coho ESU would be directly affected by all construction-related activities. Adverse effects to riparian zones would be mid- to long-term or permanent depending on whether mid-seral riparian forests (46 acres) or LSOG riparian forests (17 acres) are removed; and
- a failure of crossing isolation structures lasting up to 6 hours could cause a SEV score of 7 (moderate habitat degradation) or higher for at least 542 meters downstream from dry open cut crossings within seven streams with critical habitat in the Coos Bay Frontal-Pacific Ocean watershed; 1,185 meters of three streams crossed by dry open-cut with critical habitat within the North Fork Coquille River watershed; 1,999 meters of two streams crossed by dry open-cut with critical habitat within the East Fork Coquille River watershed; 1,534 meters of two streams crossed by dry open-cut with critical habitat within the Olalla Creek-Lookingglass Creek watershed; 856 meters of four streams crossed by dry open-cut with critical habitat within the Clark Branch-South Umpqua River watershed; 1,544 meters of three streams crossed by dry open-cut with critical habitat within the Myrtle Creek watershed; and 16 meters of four streams crossed by dry open-cut with critical habitat within the Days Creek-South Umpqua River watershed.

3.5.5 Lost River Sucker

3.5.5.1 Species Account and Critical Habitat

Status

The Lost River sucker was listed as a federally endangered species on July 18, 1988 (FWS 1988). The Lost River sucker was listed as endangered because of the loss of habitat and access to historical range, resulting in a declining population. A five-year review was released in August 2013 recommending no change to the current listing status as endangered.(FWS 2013k).

Threats

Lost River suckers and shortnose suckers were considered together in the final rule listing both as endangered species. Numerous factors in both species' decline were cited by FWS (1988) including historical over-fishing, dams limiting upstream movements and access to spawning habitats, introduction of non-native species that compete (fathead minnows) and prey on suckers (yellow perch, bullheads, largemouth bass, and various lepomid sunfish), and degradation of water quality due to livestock grazing, agriculture, and timber harvest. Pollution in Upper Klamath Lake has led to algal blooms with increased mortality of suckers when oxygen depletions occur due to eutrophication. Status assessments conducted in 2001 and 2002 (FWS 2002a) concluded that the Lost River sucker was threatened by the following: 1) drastically reduced adult populations and reduction in range; 2) extensive habitat loss, degradation, and fragmentation; 3) small or isolated adult populations as a result of dams; 4) poor water quality; 5) lack of sufficient recruitment; 6) entrainment into irrigation and hydropower diversions; 7) hybridization with the other native Klamath sucker species; 8) potential competition with introduced exotic fishes; and 9) lack of regulatory protection.

Many of these same issues remained as factors threatening the species' recovery in 2013 (FWS 2013k). Regulatory protection of aquatic habitats inhabited by Lost River suckers has improved with implementation of various state (Oregon and California) and federal laws that minimize effects of actions on the species and habitat during project planning and consultation. However, Lost River suckers continue to be affected by adverse water quality, habitat degradation, toxicity from blue-green algae, and entrainment into irrigation and hydropower diversions. Added to the earlier threats listed is climate change which is predicted to increase flows during winter months but decrease flows during the spawning period, from March or mid-April through May (FWS 2013k).

Two recent significant habitat improvements have been the removal of the Chiloquin Dam and restoration and reconnection of the Williamson River Delta. Additionally, about 400 habitat restoration projects have been completed or are planned for the Upper Klamath Lake Basin. The Lost River sucker has been observed using the 6,000-acre habitat area of Williamson River Delta to Upper Klamath Lake suggesting the importance of this habitat improvement for the species. Because these efforts are so recent, population-level effects have not yet been observed. However, these actions and others are believed to be significant for the improved status of this species (FWS 2013k). Nevertheless, poor water quality in Upper Klamath Lake and the Lost River continues to threaten the viability of the species. The water quality issues are most pronounced during summers when high temperatures combined with nutrient loading from pumping diked wetlands and runoff from farms, roads, and other sources cause detrimental water quality for fish. Also, lake sediments create hypereutrophic conditions which lead to depletions of dissolved oxygen and fish die-offs (FWS 2007e and 2013k). A cyanobacterium, now present in Upper Klamath Lake, undergoes massive algal blooms; photosynthesis during daylight can supersaturate water with dissolved oxygen and respiration at night can deplete dissolved oxygen with both events deleterious to Lost River suckers (FWS 2013k). Blue-green algal or cyanobacter toxins (Microcystin) have recently been found to affect liver, intestines, kidneys, heart, spleen and gills of suckers (FWS 2013k).

Population levels were estimated to be 11,000 to 23,000 at the time of listing (FWS 2013k). This was considered a substantial decline from historic levels, but these and historic estimates may not be completely accurate (FWS 2007e and 2013k). The factors contributing to the decline include the following: habitat loss of approximately 77 percent of historic range, restricted access to spawning habitat, overharvest, and increased rates of mortality resulting from entrainment in water management structures and severely impaired water quality (FWS 2007e and 2013k). All known populations across the range of current distribution have chronically low recruitment, reduced survivorship of adult fish, and reduced age-class diversity (FWS 2013k). Length-frequency analysis suggests that the last substantial recruitment to the spawning population occurred during the late 1990s (FWS 2012f). Recent additional threats to both Lost River and shortnose sucker include climate change that contributes to changes in water flow, bird predation, algal toxins and various forms of parasitism (NMFS and FWS 2013, FWS 2013k).

Species Recovery

A recovery plan for Lost River sucker and short-nose sucker was finalized on March 17, 1993 (FWS 1993b). Since then, additional information, prompted revision of the recovery plan (FWS 2012f). The recovery program goal is to stop the population decline and enhance Lost River sucker and shortnose sucker populations so that ESA protection is no longer necessary. Actions described in the recovery plan that would aid in the delisting of the Lost River sucker include improving habitat conditions through rehabilitating riparian areas and improving land management practices in the Klamath Basin watershed, developing and achieving water quality and quantity goals, and improving fish passage, spawning habitat, and other habitat conditions. Compounding effects from drought and water diversions affect lake water levels and unscreened water diversions and fish entrainment continue as threats. Substantial entrainment occurs at the river gates of the Link River Dam (FWS 2013k). Some of the suckers that pass through the gates pass downstream to the Keno Reservoir and farther along the Klamath River where they cannot return upstream. Nevertheless, there is a small population inhabiting Lake Ewauna, probably fish that survived passage through the Link River Dam and other hydroelectric canals and turbines (FWS 2013k).

Adult populations are limited by extremely low recruitment as well as by high levels of stress and mortality associated with severely impaired water quality. As a whole the species is potentially limited by the lack of habitat connectivity (FWS 2012f). However, one of the main passage barriers that reduced access to 95 percent of its river spawning habitat, the Chiloquin Dam on the Sprague River, was removed in 2008 (NMFS and FWS 2013).

Demographic-based objectives include increasing larval production, individual survival and recruitment to spawning populations, and ultimately increasing abundance in spawning populations. The objectives of restoring spawning and nursery habitat, expanding reproduction, reducing the negative impacts from water quality on all life stages, clarifying the effects of other species on all life stages, reducing entrainment, and establishing auxiliary populations comprise the threats-based objectives. The recovery strategy is intended to produce and document healthy, self-sustaining populations by reducing mortality, restoring habitat (including spawning, larval and juvenile habitats), and increasing connectivity between spawning and rearing habitats. It also involves ameliorating adverse effects of degraded water quality, disease, and non-native fish. The plan provides areas of emphasis and guidelines to direct recovery actions (FWS 2012f).

There are two recovery units for Lost River suckers, the Upper Klamath Lake Unit and Lost River Basin Unit (FWS 2012f). Upper Klamath Lake Unit includes all Lost River suckers within the lake, tributaries to Upper Klamath Lake, and reservoirs within the Klamath River including Keno Reservoir and populations below Keno Reservoir. The Lost River Basin Unit includes Clear Lake Reservoir and tributaries including Willow Creek and Boles Creek, Tule Lake, Gerber Reservoir and tributaries, and the Lost River mainstem (FWS 2012f) even though the Lost River is not included in designated critical habitat. The Lost River proper includes individual suckers in the mainstem downstream from the Clear Lake Dam to Anderson-Rose Diversion Dam, including the Lost River tributary Miller Creek, downstream from Gerber Dam. The population in the Lost River drainage below Clear Lake Dam is comprised mostly of adults (FWS 2012f).

Life History, Habitat Requirements, and Distribution

Lost River suckers are native to the Lost River and Upper Klamath River Basin but have adapted to lake habitats and are now a lake-dwelling fish that migrates into streams to spawn (Moyle 2002). It is a long-lived species, reaching ages over 30 years. Historically, Lost River suckers were found in the Lost River watershed, Tule Lake, Lower Klamath Lake, and Sheepy Lake. The present distribution of the Lost River sucker includes Upper Klamath Lake and its tributaries, Clear Lake Reservoir and its tributaries, Tule Lake and the Lost River up to Anderson-Rose Diversion Dam, the Klamath River downstream to Copco Reservoir, and probably Iron Gate Reservoir. In the Upper Klamath Lake watershed, the Lost River sucker spawning runs are primarily limited to Sucker Springs in Upper Klamath Lake and the Sprague and Williamson Rivers. Spawning runs also occur in the Wood River and in Crooked Creek (in the Upper Klamath Lake watershed). An additional run may occur in Sheepy Lake in the Lower Klamath Lake watershed and spawning has been documented in the Clear Lake watershed (FWS 1988 and 1993b).

Although sucker spawning habitat in the Lost River is very limited, Reclamation (Reclamation 2007) has documented sucker spawning below Anderson-Rose Diversion Dam, in Big Springs near Bonanza, and at the terminal end of the West Canal as it spills into the Lost River. Suitable spawning habitats with riffle areas and rocky substrates include the spillway area below Malone Dam, immediately upstream of Keller Bridge, immediately below Big Springs in the Lost River, below Harpold Dam, and adjacent to Station 48 (Reclamation 2007). Suckers are primarily bottom dwellers, remaining within 1 foot of bottom substrates. Water depths and turbidity provide cover in lakes while pools and overhanging banks provide cover features in streams. In Tule Lake, most depths are less than 1 meter and adult suckers are confined to the few locations where depths exceed 1 meter (Reclamation 2007). During periods of deteriorating water quality, especially in Upper Klamath Lake, adult suckers may utilize shallow waters with suitable water quality even though they may be more vulnerable to predators (Reclamation 2007).

Most spawning by Lost River suckers lasts from late February to early June in the larger tributaries of inhabited lakes (FWS 2007e). River spawning habitats include riffles or runs with gravel or cobble substrate, with moderate flows, and in water 8 to 50 inches deep. Some Lost River suckers have been noted to spawn in lakes, particularly at springs occurring along the shorelines (FWS 2007e). Each Lost River sucker female may produce between 44,000 and 236,000 eggs in a single spawning season; larger, older females produce more eggs and contribute more to recruitment than younger females (Reclamation 2007).

Larval Lost River suckers are present in Upper Klamath Lake from the beginning of May through mid-July. During that period, larvae utilize protective emergent vegetation along lake shorelines which provides cover from predators, currents, and turbulence and are areas of concentrated prey including zooplankton, macroinvertebrates, and periphyton (Reclamation 2007). Similar relationships within the Lost River watershed, including Tule Lake and Lost River, have not been studied but are assumed to be similar to those in Upper Klamath Lake (Reclamation 2007).

By mid-summer larval suckers have become juveniles, which, in Upper Klamath Lake, tend to occupy shoreline habitats less than 4 feet deep with and without emergent vegetation and/or shoreline vegetation. Abundance of juvenile suckers in the lake declines dramatically during late summer and early autumn. Some of the decline is due to emigration of juveniles into the Link River and parallel canals at the outlet of Upper Klamath Lake (Reclamation 2007). Adult suckers (and presumably subadults) in Upper Klamath Lake tend to inhabit deeper (>1 meter) waters in the northern half of the lake (Reclamation 2007). But, when water quality deteriorates in the north end of the lake during mid-summer with lower concentrations of dissolved oxygen, adult Lost River and shortnose suckers migrate to relatively shallow waters in Pelican Bay along the west shore (Reclamation 2007). Similar seasonal movements have not been described for suckers inhabiting Tule Lake and the Lost River although reproduction has been documented in Tule Lake and is suspected to occur in the Lost River.

In the Upper Klamath Subbasin (HUC 18010206), Lost River suckers are found in the Klamath River as far downstream as Copco Reservoir (RM 199) and possibly Iron Gate Reservoir (RM 191). The Pipeline would cross the Klamath River at RM 249. In the Lost Subbasin (HUC 18010204), Lost River suckers are found in the Lost River mainstem and Clear Lake Reservoir (Moyle 2002). In the Pipeline project vicinity, Lost River suckers spawn in the Lost River and are present in John C. Boyle Reservoir at RM 225, downstream from the Pipeline crossing (NRC 2004). In addition to collections of Lost River suckers in J.C. Boyle Reservoir, ORBIC (2017c) cites records of collections in Lake Ewauna and in the Lost River Diversion Channel connecting the Klamath River (at RM 249.8) to the Lost River at the Lost River Diversion Dam, approximately 10 river miles downstream from the pipeline crossing of the Lost River at RM 9.5.

Historically, Lost River suckers migrated in the Lost River upstream from Tule Lake (in California) to spawn near Olene and Big Springs near Bonanza (in Oregon), but Anderson-Rose Diversion Dam now blocks the migration. Lost River suckers presently occur within Tule Lake, but the population in the Lost River drainage below Clear Lake Dam is comprised mostly of adults and the Lost River functions as a population sink with no likely chance of being self-sustaining because of low recruitment and lack of access to spawning habitats (FWS 2012f). In the early 1990s, Lost River suckers were reported spawning over cobbles in the Lost River below Anderson-Rose Diversion Dam (RM 17.4) south of Merrill, Oregon and approximately 7.6 river miles downstream from the pipeline crossing of the Lost River (ORBIC 2017c). Suckers also spawn below Malone Dam, downstream from Clear Lake, also in California.

Population Status

The Lost River sucker population in Upper Klamath Lake was estimated between 11,000 and 23,000 at the time of the Final Rule listing the species as endangered (FWS 1988). That estimate was probably inaccurate although adults in Upper Klamath Lake and Clear Lake (in California) probably numbered in the tens of thousands (FWS 2007e). There had been several die-offs during the 1990s which affected the spawning population of older adults in Upper Klamath Lake. More recent information indicates possible increased recruitment of males and females with only slight population growth in the portion of the population normally spawning along the lakeshore of Upper Klamath Lake and low recruitment continues as a major concern (FWS 2007e). Limited information indicates declines of large adult suckers in Clear Lake (FWS 2007e). Lost River suckers are known to be present in J.C. Boyle Reservoir, Copco Reservoir, and Iron Gate Reservoir but reproduction in any of the reservoirs is unknown and they are not abundant in any of the three reservoirs (Reclamation 2007).

In the past, the Lost River was probably important spawning habitat for Lost River suckers migrating upstream from Tule Lake. Now, Lost River is highly modified, used primarily for distributing irrigation water, and impaired by surface runoff and agricultural drainage (Reclamation 2007). For several years there was no indication that Lost River or shortnose suckers continued to inhabit Tule Lake, but in 1991 both species were observed spawning below Anderson-Rose Diversion Dam, and sampling at Tule Lake in the early 1990s determined that small populations of both species were present (Reclamation 2007). Lost River sucker spring-spawning abundance in 2007 was estimated to be 56 percent and 75 percent of 2002 abundances for males and females respectively (FWS 2012f). Tagging studies conducted on Lost River suckers and shortnose suckers in Gerber Reservoir and Clear Lake Reservoir (both impoundments are connected to the Lost River below Gerber Dam and Clear Lake Dam, respectively) indicate that numbers of large adult suckers of both species have declined since 2000. Declines in large adult Lost River suckers have been particularly pronounced in Clear Lake Reservoir, possibly due to poor recruitment from younger age classes prior to 2000 (Barry et al. 2009).

Hewitt et al. (2015) estimated λ and other population demographic properties for the adult spawning population of Lost River suckers in Upper Klamath Lake from 2001 to 2012 (figure 3.5.5-1). In the figure, the population rate of change ($\lambda = N_{t+1} / N_t$) indicates positive or negative growth. When $\lambda > 1$, the rate of change is positive and the population (N) has grown from N_t to N_{t+1} in the next time interval. Alternatively, the population is stable when $\lambda = 1$, but when $\lambda < 1$, the population has declined from N_t to $N_{t+1.}$ The data show a declining adult spawning population but do not indicate changes in the whole population because they do not account for changes in the numbers of juveniles from year to year. With additional demographic data, Hewitt et al. (2015) concluded that the spawning population in the Upper Klamath Lake consisted "almost entirely of similarly sized individuals growing through time, with little evidence of recruitment."

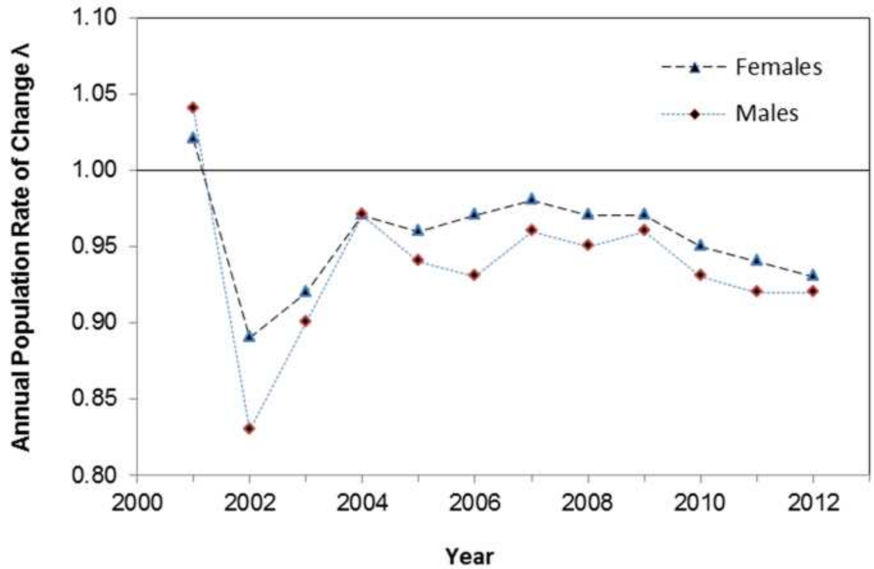

Figure 3.5.5-1. Estimates of Annual Population Rate of Change (λ) for Lost River Suckers from the Lakeshore Spawning Subpopulation, Upper Klamath Lake, Oregon. The Population is declining when λ < 1 (data from Hewitt et al. 2015).

Critical Habitat

Critical habitat for Lost River and shortnose suckers was designated in 2012 (FWS 2012g). Along the route of the Pipeline, designated critical habitat for Lost River and shortnose sucker (Unit 1 in Klamath County) includes the Link River, Lake Ewauna, and Klamath River downstream to Keno. Unit 2, in Klamath and Lake Counties, Oregon and Modoc County, California, includes Clear Lake Reservoir and tributaries and Gerber Reservoir and tributaries but does not include the Tule Lake and its tributary, the Lost River. For reasons described above (blockage by Anderson-Rose Diversion Dam), neither Tule Lake or Lost River provides spawning habitats or supports viable self-sustaining populations of Lost River suckers or shortnose suckers (FWS 2012g). The Pipeline does not coincide with critical habitat in Unit 2.

In Unit 1 (Upper Klamath Lake), there are 13 miles of critical habitat on federal land, less than 1 mile on state land, and 106 miles on lands of private/other ownership. In Unit 2 (Lost River Basin), there are 23 miles of critical habitat on federal land, less than 1 mile on state land, and 3 miles on lands of private/other ownership (FWS 2012g).

PCEs of critical habitat include (FWS 2012g):

1. **Water**. Areas with sufficient water quantity and depth within lakes, reservoirs, streams, marshes, springs, groundwater sources, and refugia habitats with minimal physical, biological, or chemical impediments to connectivity. Water must have varied depths to accommodate each life stage: Shallow water (up to 3.28 feet [1.0 meter]) for larval life stage and deeper water (up to 14.8 feet [4.5 meters]) for older life stages. The water quality characteristics should include water temperatures of less than 82.4°F (28.0°C); pH less than 9.75; dissolved oxygen levels greater than 4.0 mg/l; low levels of microcystin;

and un-ionized ammonia (less than 0.5 mg/l). Elements also include natural flow regimes that provide flows during the appropriate time of year or, if flows are controlled, minimal flow departure from a natural hydrograph.

2. **Spawning and rearing habitat**. Streams and shoreline springs with gravel and cobble substrate at depths typically less than 4.3 feet (1.3 meters) with adequate stream velocity to allow spawning to occur. Areas containing emergent vegetation adjacent to open water provide habitat for rearing and facilitate growth and survival of suckers as well as protection from predation and protection from currents and turbulence.
3. **Food**. Areas that contain an abundant forage base, including a broad array of chironomidae, crustacea, and other aquatic macroinvertebrates.

3.5.5.2 Environmental Baseline

Analysis Area

For Lost River suckers, the riverine analysis area is limited to fresh waterbodies within the Upper Klamath Subbasin (HUC 18010206; see figure 3.5.5-2A) and Lost Subbasin (HUC 18010204; see figure 3.5.5-2B). The riverine analysis area includes two components: 1) the water column and substrate of all waterbodies crossed by the Pipeline from the point of crossing to the extent downstream where water quality is adversely affected by turbidity generated during construction and sediment generated by runoff from the construction right-of-way, and 2) waterbodies' associated riparian zones affected in the short-term during construction and in the long-term by operation. The riverine analysis area for the Lost River sucker includes two perennial flowing river crossings (Klamath River and Lost River) which likely have Lost River suckers present at the time of constructions. In addition to the two perennial waterbodies, the Pipeline would also cross 83 intermittent streams, ditches and canals; 23 additional intermittent streams, ditches, ponds and canals would be adjacent to the Pipeline, within the construction right-of-way but not crossed. There is no information to indicate that Lost River suckers occur in any of these intermittent waterbodies but they are included in the riverine analysis area for Lost River suckers.

Species Presence

The Lost River sucker has been documented within the Klamath River from Klamath Falls to Keno Reservoir (FWS 2013k). The Pipeline would cross the Klamath River at RM 249. The Lost River sucker is also known to be present from Tule Lake Sump and Clear Lake Reservoir in northern California, which are connected by the Lost River. Tule Lake Sump is at the lower terminus of the Lost River and the population in Tule Lake is isolated from upstream spawning areas by multiple dams including blockage by the Anderson-Rose Diversion Dam.

Historically, Tule Lake supported large populations of Lost River suckers but much of the historical lake bed area has been drained and transformed to agriculture and portions were engineered to receive high runoff flows from the Klamath River via the Lost River Diversion Channel and Lost River (Hodge and Buettner 2009). Dams constructed on the Lost River, including the Lost River Diversion Dam, Anderson-Rose Diversion Dam, Malone Dam, and Harpold Dam have blocked suckers from accessing spawning areas upstream in the Lost River.

Currently, Lost River sucker spawning migrations are limited from Tule Lake to the Lost River below the Anderson-Rose Diversion Dam. Lost River suckers migrate a short distance from Tule Lake to spawn in the Lost River below Anderson-Rose Diversion Dam (RM 17.4) south of

Merrill and approximately 7.6 river miles from the Pipeline crossing of the Lost River (ORBIC 2017b). As of 2006, Lost River suckers had not been detected in the Lost River from the Lost River Diversion Dam to Anderson-Rose Diversion Dam, a reach that coincides with the proposed crossing of the Lost River (FWS 2013k). Lost River suckers continue to occupy the Lost River below Anderson-Rose Diversion Dam to Tule Lake.

Very little water flows in the Lost River below the Lost River Diversion Dam except during the winter and early spring. During the irrigation season, all flows are diverted at Anderson-Rose Diversion Dam into the J-Canal for irrigation deliveries to the Tule Lake Irrigation District (Hodge and Buettner 2009). From 2006 to 2008, FWS and Reclamation placed gravels below the Anderson-Rose Diversion Dam and released flows from mid-April to early June to entice suckers to migrate from Tule Lake and spawn in the lower Lost River. Lost River suckers and shortnose suckers sporadically spawned in the graveled riffle area below the Anderson-Rose Diversion Dam and sucker larvae were documented in the Lost River during 2006 although they may have derived from Upper Klamath Lake, the Upper Lost River, and/or Clear Lake Reservoir. Reclamation salvages suckers from J-Canal, which drains into Tule Lake, suggesting that some entrained fish move into Tule Lake (Hodge and Buettner 2009).

Tagged Lost River suckers spawning in the lower Lost River peaked from late April to mid-May and from late May to early June (Hodge and Buettner 2009). Most of the suckers that migrated into the Lost River from Tule Lake moved to below the Anderson-Rose Diversion Dam and spawn there. Larval suckers were present from May 30 to July 22, 2008. The population of Lost River suckers in Tule Lake Sump is probably in the low thousands of individuals which is higher than documented in the early 1990s (Hodge and Buettner 2009). Currently, Tule Lake functions only as a sink for Lost River sucker populations (FWS 2012g).

Regular spawning occurs in the Upper Klamath Lake and in Clear Lake Reservoir. Recruitment is low for the spawning population in Upper Klamath Lake. Clear Lake Reservoir, in California, supports a sustaining population of Lost River suckers that is critical to the species' recovery (FWS 2012f; Barry et al. 2009). Growth rates for adult Lost River suckers are greater in Clear Lake Reservoir than in Upper Klamath Lake, possibly due to younger individuals present in Clear Lake (Barry et al. 2009). Suckers spawn in Willow Creek, a tributary to Clear Lake Reservoir, during February and March when water temperatures range from 4^{o}C to 12^{o}C and larva emigrate down Willow Creek into Clear Lake Reservoir from late March to mid-April (Perkins and Scoppettone 1996). There is limited evidence of a resident population of Lost River suckers in the Lost River above Malone Dam in the Langell Valley, Oregon (FWS 2012g). However, Lost River suckers are prevented from accessing historically occupied habitats in Lost River mainstem and lower Lost River from Clear Lake Reservoir by the Malone Dam.

Historically, dewatering of canals, laterals, and drains has included biological monitoring and salvage of listed species, as needed. Canals, laterals, and drains are dewatered at the end of irrigation season which includes capture and relocation (salvage) of suckers from the canal system after dewatering occurs. Nearly all canals, laterals, and drains are either dewatered after the irrigation season, before April and after October, or have the water lowered for inspection and maintenance (NMFS and FWS 2013). Canals remain dewatered until the following spring (as early as late March) except for the input of localized precipitation-generated runoff (NMFS and FWS 2013). Reclamation's fish salvage efforts focus on the A Canal forebay in front of the fish screen, C4 Canal, D1 Canal, and D3 Canal within the Klamath Irrigation District, and J Canal within the Tule Lake Irrigation District (NMFS and FWS 2013). The Pipeline would cross the C-4-E Lateral at MP 201.63, the C-4 Lateral at MP 204.12, the C-4-F Lateral at MP 204.33, and the C-4-C Lateral at MP 205.50 in the Lake Ewauna-Klamath River watershed. In addition, the Pipeline would cross the C Canal at MP 205.96 and the C-4-7 Lateral at MP 207.40 in the Mills Creek-Lost River watershed. All six canals and laterals are presumed to be associated with the C4 Canal and may be occupied by Lost River suckers prior to dewatering. The Pipeline would not cross the A Canal, D1 Canal, the D3 Canal, or the J Canal.

Past efforts have shown that salvage of suckers is practical in some locations, but numbers of salvaged suckers are highly variable among years and sites (NMFS and FWS 2013). Occurrence of Lost River suckers in canals and ditches operated and maintained by Reclamation is possible if they are crossed before dewatering begins in October. However, based on the unpredictability of Lost River sucker occurrence at any one site at any specific time, there is no way to anticipate the species' presence during Pipeline construction. All canals, laterals, and drains operated and maintained by Reclamation would be crossed using conventional bores, thus avoiding any instream construction and conflicts with Lost River suckers if present. Irrigation ditches and roadside ditches on private land would be crossed by dry open-cut construction if water is present at the time. The connectivity of those ditches with canals, laterals, and drains operated and maintained by Reclamation is unknown, but because of their small size and functions as agricultural drains, Lost River suckers are not expected to occur.

A total of 26 streams/ditches in the Lake Ewauna-Klamath River watershed and 59 streams/ditches in the Mills Creek-Lost River watershed would be crossed (85 total) by the Pipeline. The right-of-way would not cross but would be adjacent to 23 additional streams/ditches in the two watersheds. Altogether, the Pipeline would potentially affect 108 waterbodies in the range of the Lost River sucker (see table 3.5.5-1). All but the Klamath River and Lost River have intermittent flow. There are 106 intermittent streams or ditches between MPs 188.9 and 228.1; 58 of them would be crossed by dry open cutting and 25 of them would be crossed using a conventional bore (with no instream construction). Twenty-three intermittent streams/ditches/canals would not be crossed but are present within the construction right-of-way (see table 3.5.5-1). They are expected to be dry at the time of construction.

TABLE 3.5.5-1

Waterbodies Crossed or Adjacent to the Pipeline within the Lake Ewauna- Klamath River Watershed (HUC 1801020412) and Mills Creek-Lost River Watershed (HUC 1801020409) in the Range of the Lost River Sucker and Shortnose Sucker

Waterbodies Crossed and Waterbody ID	NHD Waterbody Reach Code and/or Jurisdiction	Pipeline Milepost (MP)	Waterbody Type	Proposed Crossing Method a/ (potential for blasting) d/	Species Present b/	Fishery Construction Window c/

a/ Dry open cut crossing methods include flume or dam-and-pump procedures. Dam-and-pump methods would be utilized where streambed blasting is anticipated to eliminate blasting around the flume. The dam-and-pump crossing method is the preferred crossing procedure in steep incised drainage valleys where worker safety may be compromised when placing ("threading") the pipe string under the flume pipe and where there is a risk of upsetting the flume during this operation. The dam-and-pump crossing method is also the preferred crossing method on small streams under low flow conditions during the recommended ODFW-recommended in-water work period. PCGP proposes temporary/short-term fish passage restriction when completing dam-and-pump crossings within the ODFW-recommended in-water work period.

b/ ORBIC (2017b)

c/ Assumes fisheries construction windows only apply to those waterbodies flowing at the time of construction and windows do not apply to HDD crossings.

d/ Streambed bedrock based on PCGP's Wetland and Waterbody delineation surveys. Streambed bedrock may require special construction techniques to ensure pipeline design depth. Special construction techniques may include rock hammering, drilling and hammering, or blasting. The need for blasting would be determined by the construction contractor and would only be initiated after ODFW blasting permits are obtained.

Habitat

The Lost River has been highly altered to meet the needs of agriculture and to reduce the threat of flooding, and therefore habitat is fragmented and disconnected by dams lacking fish passage (NMFS and FWS 2013). Much of the water flowing through the lower Lost River channel comes from Upper Klamath Lake through the A Canal. Consequently, water in the Lost River is high in nutrients and is reused many times by different users causing nutrient concentrations to be increased. Water flowing in the Lost River eventually empties into the Tule Lake NWR as return flow from irrigation (no water is released through the Anderson-Rose Diversion Dam) and can be pumped to the Lower Klamath NWR before flowing to the Klamath River via the Klamath Straits Drain (NMFS and FWS 2013). The extensive alterations of the Lost River watershed, along with inputs from Upper Klamath Lake and agricultural drainage, have contributed to seasonally poor water quality, and the Lost River is listed by the State of Oregon for exceedances in temperature, dissolved oxygen (DO), pH, algal biomass, and ammonia toxicity (NMFS and FWS 2013).

Dams continue to limit passage and sucker migration, impose isolation of subpopulations, and decrease available spawning habitats which raise the possibility of facilitating hybridization between several sucker species. Dams may also cause stream channel changes, alter water quality, and provide habitat for exotic fish that prey on suckers or compete with them for food and habitat. Although there are seven major dams in the Klamath Basin that may affect the migration patterns of listed suckers, only the Link River Dam has been recently equipped with a fish ladder that was designed specifically for sucker passage. Fish ladders are present at J.C. Boyle and Keno dams and, although suckers have been observed to use the ladders, they were not designed for sucker passage and generally are inadequate for sucker passage (Reclamation 2007).

Lost River suckers continue to inhabit the Klamath River above Keno. Lost River suckers may enter the Klamath River from Upper Klamath Lake by passing through the gates at Link River Dam. Lost River suckers that survive passing through the hydroelectric facilities either die due to poor summer water quality conditions or pass downstream into the Klamath Reservoirs. At that point, fish are unlikely to return and believed to be lost from the breeding population (FWS 2007e and 2013k). The Pipeline would cross the Klamath River using HDD.

Adverse water quality is the most critical threat to the Lost River sucker (FWS 2007e). Klamath River and Klamath Lake have been designated as water quality impaired, including for nutrient loads which are enhanced by drainage of irrigation water from agricultural lands adjacent to Klamath Lake. Construction of dikes and drainage systems converted wetlands to agricultural use. Soils high in organic content were subject to mineralization processes which released nutrients into the aquatic system, especially phosphorous and nitrogen (Rykbost and Charlton 2001).

High levels of phosphorous in Klamath Lake have led to extreme eutrophication events that promote algal blooms dominated by the blue-green algae, *Aphanizomenon flos-aquae,* that reach or nearly reach theoretical biological maxima (NRC 2004). As a consequence, portions of Upper Klamath Lake develop conditions of oxygen depletion or are anoxic, and accumulate high concentrations of ammonia which has resulted in mass mortality of fish, including adult suckers (NRC 2004). Lost River suckers are likely to experience high mortality if exposed to one or more of the following: pH $\geq$ 9.8, ammonia (unionized) concentration $\geq$ 0.34 mg/l, water temperatures $\geq$29.4^{o}C ($\geq$85^{o}F), and dissolved oxygen (DO) concentration $\leq$ 2.3 mg/l (Bellerud and Saiki 1995). Seasonally low DO concentrations occur throughout the Lost River, and can be especially low in reservoirs where concentrations < 2 mg/L have been reported as lasting from a day to several weeks in Anderson-Rose, Harpold, and Wilson reservoirs, with DO concentrations near 0 mg/L observed in some reservoirs (NMFS and FWS 2013).

No assessments have been conducted for either of the two fifth-field watersheds that would be crossed by the Pipeline in the Lost Subbasin: Lake Ewauna-Klamath River (HUC 1801020412) and Mills Creek-Lost River (HUC 1801020409). Likewise, no stream reaches have been sampled under ODFW's Aquatic Inventories Project in either of the fifth-field watersheds. Nevertheless, modifications and degradation of aquatic habitats have been documented by FWS (1993b and 2012f), USGS (Dileanis et al. 1996), Reclamation (2007), and the NRC (2004).

Dams limit passage and fish migration, impose isolation of subpopulations, and decrease available spawning habitats (Reclamation 2007). Klamath River and Klamath Lake have been designated as water quality impaired, including for nutrient loads which are enhanced by drainage of irrigation water from agricultural lands adjacent to Klamath Lake. Construction of dikes and drainage systems converted wetlands to agricultural use. Soils high in organic content were subject to mineralization processes which released nutrients into the aquatic system, especially phosphorous and nitrogen (Rykbost and Charlton 2001). Sediment accumulation rates in Upper Klamath Lake indicate substantial annual increases since the late 1880s due to deforestation, drainage of wetlands, agriculture, livestock production and irrigation (Reclamation 2007).

High levels of phosphorous in Klamath Lake have led to extreme eutrophication events that promote algal blooms dominated by the blue-green algae, *Aphanizomenon flos-aquae,* that reach or nearly reach theoretical biological maxima (NRC 2004). As a consequence, portions of Upper Klamath Lake develop conditions of oxygen depletion or are anoxic and accumulate high concentrations of ammonia which has resulted in mass mortality of fish (NRC 2004).

There are no recent long-term water discharge data for waterbodies in the Lost River watershed. The A Canal connects the Link River to the Lost River via the B Canal. According to USGS Gage 11507200, there is no flow in the A Canal between November and March (see figure 3.5.5-3), corresponding to periods of water diversions from the Klamath River, discussed above.

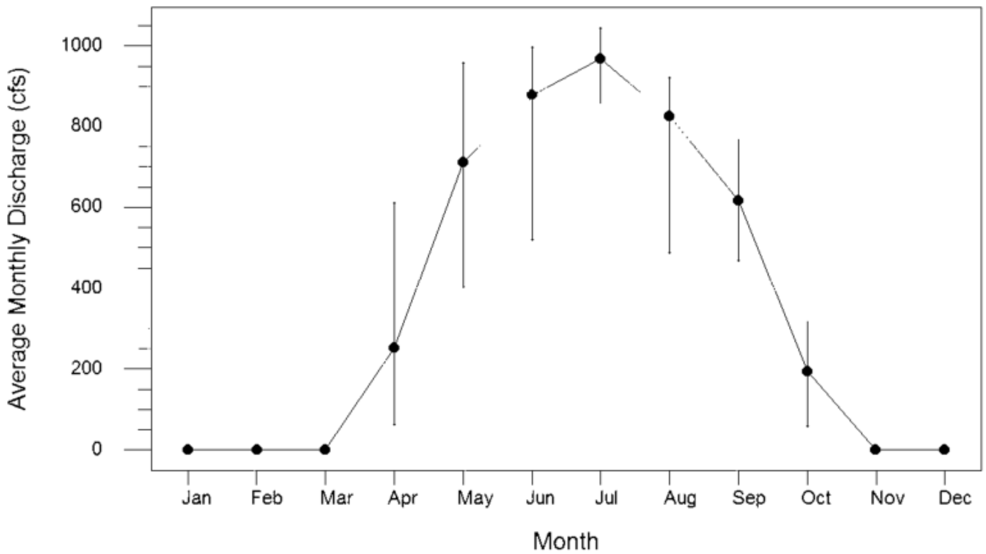

Figure 3.5.5-3 Average Monthly Discharge in the A Canal (USGS Gage 11507200) from 1960 to 1981. Vertical lines show maximum and minimum discharges for months during the periods of record.

Adequate flow and habitat conditions in the Lost River are likely during the spring and summer, with higher river flows supplemented by releases from Clear Lake and Gerber reservoirs (NMFS and FWS 2013k). Irrigation releases typically start in April. Flows in the Upper Lost River are very low during the fall and winter because flows from Clear Lake and Gerber reservoirs are considerably reduced, but winter flows do increase downstream from tributary and spring contributions (NMFS and FWS 2013).

Critical Habitat

Designated critical habitat for the Lost River sucker is present within the Pipeline project area. The Pipeline would cross the Klamath River at RM 249 which is within critical habitat Unit 1, Klamath County (FWS 2012g). Unit 1 includes Upper Klamath Lake and Agency Lake, together with some wetland habitat; portions of the Williamson and Sprague Rivers; Link River; Lake Ewauna; and the Klamath River from the outlet of Lake Ewauna downstream to Keno Dam. PCEs include (FWS 2012g):

1. **Water**. Areas with sufficient water quantity and depth within lakes, reservoirs, streams, marshes, springs, groundwater sources, and refugia habitats with minimal physical, biological, or chemical impediments to connectivity.
2. **Spawning and rearing habitat**. Streams and shoreline springs with gravel and cobble substrate at depths typically less than 1.3 m (4.3 feet) with adequate stream velocity to allow spawning to occur. Areas identified in PCE1 containing emergent vegetation adjacent to open water, which provides habitat for rearing and for growth and survival of suckers.

3. **Food**. Areas that contain an abundant forage base, including a broad array of chironomidae, crustacea, and other aquatic macroinvertebrates.

Critical habitat Unit 2 includes Clear Lake Reservoir and its principal tributary, Willow Creek. Unit 2 does not coincide with the Pipeline route.

3.5.5.3 Effects of the Proposed Action

In the riverine analysis area, only the Klamath River and the Lost River are inhabited by Lost River sucker based on available information (ORBIC 2017b), although Lost River suckers enter the canal system within both sub-basins and are regularly salvaged by Reclamation once canals are drained (Hodge and Buettner 2009). In the Lake Ewauna-Upper Klamath watershed, 19 intermittent streams would be crossed by dry open-cut and 6 others by boring. In the Mills Creek-Lost River watershed, 40 intermittent streams would be crossed by dry open-cut and 19 others by boring. There is no information documenting that Lost River suckers would be present in any of those intermittent streams, which include canals and ditches, at the time of construction (discussed above). The Lost River would be crossed using dry open-cut construction.

Direct and Indirect Effects

Timing to Life History Functions

The Klamath River (MP 199.38) and the Lost River (MP 212.07) are the only perennial waterbodies crossed by the Pipeline on Construction Spread 5. The ODFW (2008) allows instream construction in the Klamath River (above Keno) from July 1 to January 31 and in the Lost River (below Bonanza) from July 1 to March 31. PCGP has requested that the HDD crossing of the Klamath River be allowed to occur outside of ODFW's in-water construction windows to ensure that enough time is provided to successfully complete the crossings. PCGP proposes to cross the Klamath River using an HDD between July and October. The Lost River would be crossed by dry-open crossing methods during the ODFW-recommended crossing window (July 1 to March 31). Occasionally individual Lost River suckers have been found in this stream region, so it is possible that Lost River suckers may be present in the Lost River where the Pipeline would cross during the non-spawning period.

Species Presence

In the vicinity of the Pipeline, Lost River suckers occur in the Lake Ewauna-Klamath River 5th field watershed and the Mills Creek-Lost River 5th field watershed. The pipeline route crosses the Lake Ewauna-Klamath River 5th field watershed for about 17.24 miles (MPs 188.41 to 205.65) and the Mills Creek-Lost River 5th field watershed for 23.15 miles (MPs 205.66 to 228.81). The Pipeline will cross 26 waterbodies in the Lake Ewauna-Klamath River, one by HDD, six by conventional bore, and 19 by dry open-cut, and will cross 59 waterbodies in the Mills Creek-Lost River watershed, 20 by conventional bore and 39 by dry open-cut.

Potential effects to Lost River suckers inhabiting the Klamath River by HDD construction are discussed below. Because there will be no instream work for any of the conventional bore crossings, no effects to Lost River suckers are expected in those 26 streams, canals, drains or ditches that are maintained by the Bureau of Reclamation (BOR). Potential effects to Lost River suckers and shortnose suckers are possible in waterbodies crossed by dry open-cut, including the Lost River (known to be occupied by Lost River suckers) with the exception of 26 waterbodies crossed between MP 214.38 and MP 228.81. At MP 214.38, the pipeline route deviates from the general west to east direction and proceeds north, up a 9 percent slope (climbing from 4,100 feet to 4,360 feet elevation) to MP 215.04, and then continues to the east along a ridgeline (paralleling powerline corridors) to MP 228.81. In that segment, the route crosses 26 waterbodies that are intermittent headwater drainages with unlikely (due to steep slopes) or no pathways (no connectivity) for Lost River suckers to enter from lowland BOR canals, drains or ditches that might support Lost River suckers and shortnose suckers. No effects to Lost River suckers and shortnose suckers would occur by crossing those 26 waterbodies.

Potential effects to Lost River suckers are possible during dry open-cuts of 19 waterbodies crossed in the Lake Ewauna-Klamath River watershed and the remaining 13 waterbodies west of MP 214.38 crossed in the Mills Creek-Lost River watershed included in table 3.5.5-2. Except for the Lost River and one irrigation ditch at MP 194.64, none of the waterbodies have been mapped by the Klamath Project. Consequently, connectivity of those other 30 waterbodies (classified as ditches) to larger canals and laterals that may seasonally support Lost River suckers and shortnose suckers cannot be determined.

a/ Dry open cut crossing methods include flume or dam-and-pump procedures. Dam-and-pump methods would be utilized where streambed blasting is anticipated to eliminate blasting around the flume. The dam-and-pump crossing method is the preferred crossing procedure in steep incised drainage valleys where worker safety may be compromised when placing ("threading") the pipe string under the flume pipe and where there is a risk of upsetting the flume during this operation. The dam-and-pump crossing method is also the preferred crossing method on small streams under low flow conditions during the recommended ODFW-recommended in-water work period. PCGP proposes temporary/short-term fish passage restriction when completing dam-and-pump crossings within the ODFW-recommended in-water work period.

b/ ORBIC (2017)

c/ Assumes fisheries construction windows only apply to those waterbodies flowing at the time of construction

Suspended Sediment by Pipeline Crossing Methods

Potential occurrence of Lost River suckers in waterbodies crossed by dry open-cut are included in table 3.5.5-2. Dry crossing methods would result in minimal impacts, including temporary increases in suspended sediments in restricted areas. One HDD and 25 conventional bores would be installed without in-water work and would not directly affect the aquatic environment and associated species, except in the unlikely event of an inadvertent return during an HDD crossing, which could affect stream suspended sediment levels as discussed below. The Klamath River would be crossing with an HDD.

Since all streams/ditches crossed, except for the Klamath River and Lost River, are minor or intermediate channels, any construction required would be done in the dry, reducing potential for any adverse suspended sediment conditions downstream. Additionally, road crossings where fish may be present would be constructed to meet ODFW fish passage standards so fish movement would not be blocked. While some elevated sediment may occur downstream, effects would be unsubstantial to Lost River sucker due to the implementation of approved construction methods.

Suspended Sediment – Dry Open Cut

Pipeline crossings of surface waterbodies could cause some downstream turbidity and sedimentation. The type of crossing and the existing stream sediment characteristics affect turbidity and suspended sediment in streams. The dry crossing methods to be used are flumed or dam-and-pump:

- **Flume.** The flume method typically is used to cross small to intermediate flowing waterbodies that are either fish-bearing or non-fish-bearing streams. The flume technique involves diversion of stream flow into a carefully positioned steel pipe of suitable diameter to convey the maximum flow of the stream across the work area, and ensures that stream flow rate is not interrupted.
- **Dam-and-Pump.** With the dam-and-pump method, stream flow is diverted around the work area by pumping water through hoses over or around the construction work area. The goal of this technique is to create a relatively "dry" work area to avoid or minimize the transportation of heavy sediment loads and turbidity downstream of the crossing. This crossing method may be used on all waterbodies where stream flow can be diverted by pumping around the work area.

As noted in section 3.5.3.3, Coho Salmon (SONCC ESU), dry open cutting (fluming, dam-and-pump, or some combination of the two) generates small amounts of turbidity compared to wet open-cut procedures. However, adult suckers appear to prefer deep, turbid water but are often forced to utilize shallow, clear water during degraded water quality conditions in the summer (NRC 2004). The amounts of turbidity generated by dry open-cut construction may cause minor short-term adverse effects to Lost River suckers if they are within several hundred feet downstream of the Lost River crossing site. However, guidance for evaluating effects of exposure and dose of suspended sediments on catostomids (including Lost River sucker) is not available, similar to documentation for salmonids (e.g., Newcombe and Jensen 1996). Crossing of the intermittent channels are planned to occur in the dry so suspended sediment increases should be very low when flow is returned to the channels, as channel conditions would be stabilized. Should some crossing occur when flow is present, some suspended sediment levels would be more elevated. However, considering 1) the small size of these intermittent streams and ditches, 2) the short duration of construction activity at each crossing location, 3) the expectation that suckers would not be present in these streams/ditches, even when flowing (all crossings are more than two miles from flowing channels, which are irrigation channels), and 4) the apparent tolerance of this species for turbid water, any elevated suspended sediment would not cause adverse effects to Lost River suckers in these intermittent flow crossings.

There is a possibility that following construction, future flows returning to the ditches listed in table 3.5.5-2 could potentially indirectly affect suckers by mobilizing sediment replaced over the trench. Mobilized sediments could lead to downstream sediment impacts on forage species, streambank erosion and stability (geotechnical stability), and surface flow retention. However, during delineation of the ditches, field personnel reported stream gradients at ditches as <1% and many had mud substrates, both observations indicative of low instream flows and velocities in the ditches. Consequently, flows returning in the ditches after dry open-cut construction may not be sufficient to mobilize native materials replaced in the trench. PCGP (in the ECRP/appendix F) has proposed to install erosion control matting to cover channel bottoms where revegetation of the channel bottom is required. Erosion control matting, anchored with staples to the channel sides and bottom, could be similarly used at irrigation ditches to minimize risk of sediment mobilization, downstream sediment impacts on forage species (zooplankton such as cladocerans – water fleas – and benthic insects such as chironomid midge larvae and amphipods), and streambank erosion and stability. Use of erosion control matting would allow materials replaced as bottom substrate and restored ditch banks to consolidate without eroding until the matting degrades.

Suspended Sediment – HDD

The HDD installation method is considered an effective technique for avoiding in-stream impacts by eliminating the need for in-stream excavation (Reid and Anderson 1998; Reid et al. 2004). According to GeoEngineers' (2017g) analysis for construction using HDD across the Klamath River (see appendix E), the design length of the Klamath River HDD crossing would be approximately 2,300 feet. The proposed Klamath River entry point would be in an agricultural field about 950 feet east of the river bank and the exit would be an open area about 370 feet west of the river bank. The HDD design indicates there would be between 70 and 140 feet of streambed cover in the river channel over the pipe. There is no direct in-stream disturbance so no suspended sediment increases would occur unless there is an unplanned drilling failure. There is a moderate to high risk of hydraulic fracture from the entry point to about 900 feet to the west, all within the east bank of the river. The portion of HDD beneath the river would be below bedrock with low risk of a release of drilling mud (inadvertent return). The risk of inadvertent return would be moderate to high within 425 feet from the HDD exit point on the west bank of the Klamath River due to presence of stiff silt alluvium (GeoEngineers 2017g). Though the risk of releasing drilling mud directly beneath the riverbed is low, such a release could have impacts on the aquatic environment and species.

Inadvertent Release of Drilling Muds (Inadvertent Return). However, there is a potential for impact as a result of the HDD process. Drilling requires use of a drilling mud for lubrication of the bit and removal of cuttings. A non-toxic, biodegradable bentonite clay mixture makes up drilling mud. Because the drilling mud is under pressure during drilling, if the bit encounters substrate fractures or channels, it is possible for bentonite to escape from the drilled hole (termed an "inadvertent return"). Bentonite can escape to the surface through fractures in the drilled substrate. Bentonite by itself is a non-toxic drilling mud (Breteler et al. 1985; Hartman and Martin 1984; Sprague and Logan 1979) although according to Reid and Anderson (1998), the toxicity of bentonite (sodium montmorillonite) in fresh water ranges from 5,000 to 19,000 ppm (mg/liter) based on 96-hour tests for LC50 (the concentration at which 50 percent of the test population dies after 95 hours of exposure) on rainbow trout. The toxicity classifications based on LC50 values ranged from "slightly toxic" to "practically non-toxic" (Reid and Anderson 1998). In other tests, toxicities to lake whitefish and rainbow trout demonstrated threshold concentrations of 16,613 and 49,838 ppm (mg/liter), respectively (Reid and Anderson 1998). More recently, toxicity to rainbow trout (LC50, 96-hour) was reported to be 19,000 mg/l (ClearTech 2015). LC50 concentrations > 10,000 ppm would be considered "practically non-toxic" (Reid and Anderson 1998). As with any fine particulate material, bentonite can interfere with oxygen exchange by gills and the degree of interference generally increases with water temperature.

The summary by Reid and Anderson (1998) provides a substantive description of effects to streams and habitat in the cases with inadvertent returns.

Drilling mud releases during HDD construction can result from:

1. Circulation losses through highly permeable gravels;
2. Mud migration along rock joints or fractures which intersect with the river bottom;
3. Loss of pilot hole directional control resulting in the intersection with the river bottom or approach slope'
4. Drilling mud pressures exceeding ground stress, widening existing or creating new fractures (hydraulic fracturing), allowing for mud migration;
5. Substantially different elevations of entry and exit drill locations. Resulting pressure head differences can cause substantial upland leakages of drilling muds once the drill bit nears the ground surface or when it breaks the surface.

Drilling mud releases may surface through river and streambeds, wetland bottoms, or at upland locations. The volume of mud released to the surface would depend on:

1. Porosity of the substrate transporting the mud;
2. Extent and size of the porous material;
3. Pressure exerted on the mud by the hydraulic system;
4. Viscosity of the mud at the time of exposure;
5. Whether mud circulation can be maintained.

Magnitude of effects by mud releases to fish, streams and habitat would depend on the following (page numbers referenced from Reid and Anderson, 1998):

6. Toxicity of the drilling mud components and additives (pages 57-59 and Table 1);
1. Increased sediment loads (page 59);
2. Effects to hydrological conditions that would cause poor conditions for wetland plant establishment and growth (pages 59-60);
3. Release into streams and rivers could cause increases in the downstream drift of stream macroinvertebrates (page 60);
4. Effects on fish would depend on level of exposure (e.g., concentration) and duration of exposure and lifestage of fish present, timing of release, and ability of the watercourse to remove or incorporate the released muds without degrading existing habitats (page 61).

The report by Reid and Anderson (1998) summarizes the general effects, known or hypothesized, associated with drilling mud releases but does not provide specific effects associated with each of the instances of inadvertent returns cited.

Likewise, Canadian Pipeline Water Crossing Committee (1999) reported that drill mud seepage occurred in 36 of 146 HDD cases reviewed with most significant leakage occurring at the drill entry or exit points due to different pressure heads with large differences in elevation between the two points. Leakage also occurred during reaming or pull-back. However, the report did not describe the effects to fish, streams, and habitat in the cases with leakages or inadvertent returns.

Potential inadvertent returns are more common near the HDD drill entry and exit locations; however, impacts to waterbodies are minimized by locating the drill entry and exit points away from the waterbody. The probability of an inadvertent return may increase when the drill bit is working nearest the surface (see GeoEngineers 2017g), but is dependent on numerous factors including substrate characteristics, head pressure of the drilling mud, topography, elevation, and subsurface hydrology. PCGP has proposed an HDD crossing of the Klamath River and designed this crossing such that areas of greatest risk from inadvertent return are on uplands and not adjacent to the waterbody where much greater depth would be achieved, and inadvertent return potential is reduced.

Hydraulic fracture typically occurs when the drill path passes through relatively weak cohesive soils with low shear strength or very loose granular soils. Loose and silty sands and soft to medium stiff silts and clays typically have a higher hydraulic fracture potential. Medium dense to dense sands and gravels and very stiff to hard silts and clays have a low to moderate hydraulic fracture potential. Unfractured rock, because of its high shear strength, typically has a low potential for hydraulic fracture. HDD installations with greater depth or in formations with higher shear strength may reduce the potential for hydraulic fracturing (see appendix E).

If an inadvertent return occurs into the river, drilling fluid would enter the waterway causing short-term, temporary water quality impacts downstream of the Pipeline project area including sedimentation and turbidity. Should this occur, fish would likely avoid the immediate vicinity of any elevated suspended sediment within this larger river crossing area.

Sediments discharged into aquatic systems have the potential, depending on the concentrations, to cause hyperplasia, hypertrophy, and necrosis of fish gill tissues and impair fish vision making it difficult to feed and also making the fish more susceptible to predation. However, these effects typically occur after relatively long-term exposure to concentrated sedimentation. If drilling fluid accumulates in the substrate, it can adversely impact the quality and quantity of aquatic habitat available for aquatic species including salmonid spawning habitat and benthic macroinvertebrate rearing habitat. Drilling fluid that accumulates in the substrate may cover up food sources, and smother fish eggs and other aquatic life in the riverbed. However, significant impacts to substrate from inadvertent returns are not likely in large river systems because of the anticipated high water volumes and velocities within large rivers.

The rheologic properties of drilling fluid allow it to remain suspended within the water column for prolonged periods of time; thus the drilling fluid would likely settle out in very slow moving water downstream of the release. The distance of expected transport would likely prevent significant concentrations of the fluid from accumulating in one area of the Klamath River. If drilling fluid is inadvertently released into the river, the behavioral avoidance response of Lost River sucker is presumed to be triggered within the immediate vicinity of the release and the fish are expected to return and utilize the affected area shortly after the inadvertent release has been erved andPCGP developed its *Drilling Fluid Contingency Plan for Horizontal Directional Drilling Operations* (see appendix D), which describes how the drilling operations would be conducted and monitored to minimize the potential for inadvertent drilling mud releases. The HDD Contingency Plan also includes procedures for cleanup of drilling mud releases. If significant concentrations of drilling fluid are found during monitoring as a result of a release, the following possible corrective measures would be taken:

1. Deployment of containment structures, if feasible, and removal of drilling mud from substrate and streambanks if possible.
2. Increase the drilling fluid viscosity in an attempt at sealing the point at which fluid is leaving the drilled hole. The drilling operation may be suspended for a short period (i.e.,

overnight) to allow the fractured zone to become sealed with the higher viscosity drilling fluid.

3. If increasing the drilling fluid viscosity is ineffective, lost circulation materials (LCM) may be introduced into the hole by incorporating them in the drilling fluid and pumping the material down-hole. The drilling operation may again be suspended for a short period (i.e., overnight) to allow the fractured zone to become sealed with the LCMs.
4. Depending on the location of the fractured zone, a steel casing may be installed that is of sufficient size to receive the largest expected down-hole tools for the crossing. This casing installation provides a temporary conduit for drilling fluids to flow while opening the remaining section of the hole to a diameter acceptable for receiving the proposed pipe sections. To alleviate future concerns with the steel casing after the HDD installation is completed, the casing is generally extracted from the hole prior to or just after completing the HDD installation. However, there have been instances when attempts at extracting the steel casing were unsuccessful.
5. In the event drilling fluid flow is not regained through the annulus of the drilled hole and a steel casing installation is not utilized, the HDD contractor may elect to install a grout mixture into the drilled hole in an attempt to seal the fractured zone. The down-hole drilling assembly is generally extracted and existing hole is re-drilled to the point at which it had previously been drilled prior to having encountered the loss of drilling fluid.

In some instances, it may be determined that the existing hole encountered a zone of unsatisfactory soil material and the hole may have to be abandoned. If the hole is abandoned, it would be filled with cuttings and drilling fluid.

Overall, at the site of any inadvertent return, the amount of drilling mud released into a waterbody would be low. The HDD location would be under the Klamath River, with large volumes of water and moderate flows, where the drilling mud would be diluted. If an inadvertent release of drilling mud from an HDD occurred it would have minor short-term adverse effects to aquatic resources including Lost River sucker.

Entrainment and Entrapment

Waterbody crossings using the "dry" crossing methods, flume or dam-and-pump, may result in some fish being entrapped in streams. Flumes and dams would be completely installed and functioning before any instream trenching disturbance occurs. Construction across a waterbody would take up to four days using dry open cut methods, but less for small and intermediate streams. Fish inadvertently left within the dammed-off construction zone could be killed by impingement on pump intakes used to dewater the construction zone or would likely die once all water was removed. Waterbodies crossed by dry open-cut (the Lost River and 31 ditches) with known or potential species presence are included in table 3.5.5-2.

For typical crossings once streamflow is diverted through the flume pipe, but before trenching begins, fish trapped in any water remaining in the work area between the dams would be removed and released (salvaged) using the *Fish Salvage Plan* (see Fish Salvage Plan under section 3.5.5.4 or appendix T for details). Salvage methods could include seines and/or dip nets and electrofishing. Seining would be the primary method used to salvage fish but electrofishing methods may be used if all fish cannot be removed from the area potentially dewatered. The *Fish Salvage Plan* incorporates these methods to minimize adverse effects to listed fish.

Suckers as a group (family Catostomidae) appear to be susceptible to many of the same deleterious effects from electroshocking that were described above for salmonids (Snyder 2004). Although records of the effects by electroshock to Lost River suckers have not been compiled, responses by river carpsucker, longnose sucker, white sucker, and razorback sucker among others indicate that they are particularly susceptible to spinal injuries and hemorrhages by electrofishing (Snyder 2004). Reclamation has salvaged fish from canals throughout the Klamath Project each fall since 1991 following dewatering using electrofishing techniques (Reclamation 2008). Reclamation has noted that if electrofishing is found to injure juvenile suckers, they would pursue other techniques to salvage fish (Reclamation 2008). Sucker mortalities (Lost River suckers, shortnose suckers, and Klamath largescale suckers) have occurred during salvage operations, whether due to electrofishing stress or to low levels of dissolved oxygen (Peck 2000 and 2001). Reclamation has also done annual fish salvages in the forebay of a fish screen facility using backpack electrofishers and beach seines This annual salvage procedure alleviates potential mass mortality of all fish at the fish screen as water is removed (Reclamation 2007).

All methods of capture and holding have risks of stress, injury, or mortality of fish. In conjunction to implementation of the *Fish Salvage Plan*, PCGP would contract with either ODFW or a qualified consultant to capture the fish. Fish removal personnel will be approved by ODFW and NMFS for this listed species. Personnel who would handle and/or remove fish on federal lands would also be approved by the Forest Service or the BLM, or the work would be done directly by agency personnel if approved by ODFW. Overall, some listed juvenile Lost River sucker may suffer injury or mortality, but with the implementation of Pipeline project conservation measures the numbers would be slight.

Acoustic Shock and Underwater Noise

There would be no blasting or use of mounted hydraulic impact hammer to cross the Lost River where Lost River suckers may be present during crossing or any of the 31 ditches with potential species presence included in table 3.5.5-2. Use of back-hoes for dry open-cut construction would not produce sound levels to cause harm to Lost River suckers, as discussed for SONCC coho salmon in section 3.5.3.3.

Riparian Vegetation Removal, Modification and LWD Loss

Aquatic resources, including Lost River suckers and habitat components, could be affected as a result of removal of vegetation and instream habitat at the waterbody crossing sites as required for construction. Short-term, physical habitat disruption would occur during trenching activities. Long-term degradation of habitats could occur if the stream contours are modified in the area of the crossing; the flow patterns are changed; or erosion of the bed, banks, or adjacent upland areas introduces sediment into the waterbody. Loss of riparian vegetation along the banks would remove an important source of terrestrial food for aquatic organisms, and potentially increase mass slope failures adjacent to waterbodies.

Because HDD would be used to cross the Klamath River, only 0.04 acre (Urban or Built-up land) within the Klamath River riparian zone (extending 117 feet or one site-potential tree height from each river bank) would be affected. No forested riparian vegetation would be affected. Construction across the Lost River would disturb approximately 1.35 acres of agricultural land within the riparian zone (extending 119 feet from each river bank). Similar to the Klamath River crossing, no forest riparian vegetation would be affected or removed and all effects would be to agricultural land. Riparian zones associated with the Klamath River and Lost River crossings are on land owned by the State of Oregon. Riparian Zones for all other waterbodies crossed that are within range of the Lost River sucker are on private lands. All crossings other than the Klamath River and Lost River are on intermittent streams/ditches/canals with very limited low-growing riparian vegetation and would have unsubstantial reduction in near stream vegetation from crossing clearing. Likewise, as there are few trees in the riparian area along the route in the range of the Lost River sucker, there would be no change in LWD supply to any stream system from construction of right of way clearing or maintenance.

Overall, there would be no substantial change in riparian vegetation or LWD supply along the route where Lost River sucker may be present. Ecological function (e.g., supply of shade, future LWD, and organic input) of the riparian conditions would be maintained and adverse effects to Lost River sucker would not occur from right-of-way clearing at stream crossings.

Water Temperature

Lost River suckers are susceptible to high water temperatures 85°F or higher (Bellerud and Saiki 1995). As discussed above, no riparian vegetation would be removed that otherwise would provide shade. Consequently, water temperature would not be affected by construction within the Lost River and Klamath River.

Aquatic Habitat

There also are potential indirect effects to aquatic habitat from increased suspended sediment from stream crossings. As discussed for SONCC coho salmon, suspended sediment released during stream crossing construction may have downstream habitat effects as well as direct fish effects such as changing substrate conditions (e.g., elevated fines) that may affect benthic food resources. Only one stream, the Lost River, is known to be crossed with stream bottom substrate-disturbing activities during flowing periods; 31 ditches with potential for species included in table 3.5.5-2 are expected to be crossed in the dry and could have suckers present in the crossing area. While the actual magnitude of sediment generated during crossing the Lost River is not known, estimates of sediment generated by dry open-cut construction along other portions of the route and implementation of BMPs would not result in short-term sediment elevations that could have substantial downstream adverse habitat effects that would indirectly affect the Lost River sucker or the species habitat.

Freshwater Stream Invertebrates

Substrates downstream from in-stream construction sites could be impacted by sediments which could affect forage species used by Lost River suckers. Mayflies, caddisflies, and stoneflies prefer large substrate particles in riffles and are adversely affected by fine sediment deposited in interparticulate spaces (Cordone and Kelley 1961; Waters 1995; Harrison et al. 2007). Suckers feed on benthic organisms including algae and invertebrates so reductions could affect their growth and survival. Fish and benthic macroinvertebrate abundance downstream of pipeline construction sites have been reported as short-term reductions (Reid and Anderson 1999). Macroinvertebrate abundance and community composition are highly related to the degree to which substrate particles are embedded by fine material (Birtwell 1999). Data below wet open-cut crossings, which generate much higher sediment levels than dry cut crossings, generally found negative changes in benthic invertebrate populations were not apparent within a year (Reid et al. 2008) and some data found rapid recolonization of substrate within 30 days (Gartman 1984). Therefore, the overall level of effect of the pipeline crossings on waterbodies crossed by dry open-cut (the Lost River and 31 ditches) with known or potential species presence included in table 3.5.5-2 (unless sealing failures at isolation structures occur) would be even less than those noted by literature and would not result in substantial reduction in growth or survival of listed Lost River individuals.

Streambank Erosion and Streambed Stability

Clearing and grading activities during construction could increase erosion along streambanks resulting in higher turbidity levels in the waterbodies crossed. Alteration of the natural drainage ways or compaction of soils by heavy equipment near streambanks during construction may accelerate erosion of the banks, runoff, and the transportation of sediments into waterbodies. Erosion, sedimentation, and higher turbidity levels related to the Pipeline project could affect aquatic resources in waterbodies crossed by dry open-cut (the Lost River and 31 ditches) with known or potential species presence (included in table 3.5.5-2). The degree of impact on aquatic organisms due to erosion would depend on sediment loads, stream velocity, turbulence, streambank composition, and sediment particle size.

Alteration of the natural drainage ways or compaction of soils by heavy equipment near streambanks during construction may accelerate erosion of the banks, runoff, and the transportation of sediments into waterbodies. The degree of impact on aquatic organisms due to erosion would depend on sediment loads, stream velocity, turbulence, streambank composition, and sediment particle size. To minimize these impacts, PCGP would use temporary equipment bridges, mats, and pads to support equipment that must cross the waterbody (perennial, intermittent, and ephemeral if water is present) or work in saturated soils adjacent to the waterbody. PCGP would also install sediment barriers, such as silt fences and straw/hay bales, across the right-of-way at the edge of waterbodies throughout construction except for short periods when the removal of these sediment barriers is necessary to dig the trench, install the pipe, and restore the right-of way. Practices to minimize streambank erosion are provided in the ECRP (see appendix F).

The FWS expressed concerns that more detailed site-specific information on bank material, streambed composition, shoreline vegetation and other information is needed to adequately ensure that actions occurring at a stream crossing do not significantly increase streambank erosion and streambed instability. PCGP, in response to these requests, conducted an assessment of crossing conditions of all streams suitable for analysis based on the FWS risk matrix (GeoEngineers 2017d, 2017e, 2018a). As discussed for SONCC coho salmon, PCGP used this matrix to rate crossings for risk of potential stream bank and channel changes. Based on the GeoEngineers (2017d, 2017e, 2018a) Risk Matrix analysis, the Lost River crossing has a “high” level of risk based on existing stream site sensitivity based on the landscape/stream type (channel characteristics), riparian conditions (essentially none), and bed conditions (sand). If any crossing is moved into the “high” impact and “high” stream response risk matrix category, a site-specific crossing design would be developed for that site. Construction would then move forward as described in the permit documents including implementation of special additional BMPs, as described in GeoEngineers (2017d, 2017e, and 2018a), depending on individual site conditions and may include such actions as changes in bank material and bank angle modifications, specific substrate composition used, plants used on the bank, artificial stabilizing bank material, rootwad enhancement, and various other actions. These actions would reduce potential adverse effects from bank and bed stability to unsubstantial levels to the listed Lost River sucker.

Hydrostatic Testing

Water would be required on a one-time basis near the end of construction to hydrostatically test the pipeline. Potential impacts associated with hydrostatic testing include entrainment of fish; transfer of exotic organisms between basins; reduced downstream flows and impaired downstream uses if test water is withdrawn from surface waters; and erosion, scouring, and a release of chemical additives as a result of test water discharge. PCGP would obtain its hydrostatic test water from commercial or municipal sources or surface water rights owners, the sources of which are lakes, impoundments, and streams.

Within the range of Lost River sucker, there are four potential water sources, including John C. Boyle Reservoir, Keno Reservoir, Klamath River, and High Line Canal. There are 5 potential discharge locations, all of which are within the right-of-way. None of the hydrostatic test break sections are in the vicinity of a waterbody with known Lost River sucker occupancy or critical habitat. Discharge volume at each site ranges from 0.63 to 4.6 million gallons. The largest withdrawal is proposed from the Klamath River or High Line Canal. Water withdrawn from Keno Reservoir at Keno Dam will be from designated critical habitat for Lost River suckers. Water will also be withdrawn from John. C. Boyle Reservoir at the Spencer Bridge. Although the reservoir is not included in designated critical habitat, Lost River suckers are expected to be present. Water withdrawals from occupied habitats risk entrainment and impingement. The screening of intake hoses would be used to prevent the entrainment of fish and other aquatic organisms, meeting NMFS screening criteria. The rate of withdrawal would also be regulated to avoid adverse impact on aquatic resources or downstream flows (NMFS 1997c).

PCGP would minimize the potential effects of hydrostatic testing by adhering to the measures in its *Hydrostatic Testing Plan* (see appendix U). Where test water cannot be returned to its withdrawal source, the water would be treated and discharged to an upland location (at least 150 feet from wetlands or waterbodies with no direct discharge to these features) through a dewatering device at a rate to prevent scour and erosion and to promote infiltration. PCGP would obtain all necessary appropriations, withdrawal, and discharge permits through the OWRD. With the implementation of the *Hydrostatic Testing Plan* and BMPs and by obtaining required permits, adequate measures would be in place to prevent direct or indirect effects of hydrostatic testing to Lost River sucker that may be in some of the stream systems.

Aquatic Nuisance Species

NAS are aquatic species that degrade aquatic ecosystem function and benefits, in some cases completely altering aquatic systems by displacing native species, degrading water quality, altering trophic dynamics, and restricting beneficial uses (Hanson and Sytsma 2001). Currently, there are 180 reported NAS in Oregon, of which 134 are documented within the USGS hydrologic basins crossed by the Pipeline (USGS 2017).

In the riverine environments crossed by the Pipeline, largemouth and smallmouth bass, introduced as recreational species, prey on juvenile sockeye, coho, and Chinook salmon (Tabor et al. 2007). Additionally, up to 20 exotic species (many of which can reside in streams including largemouth bass, yellow perch, and fathead minnow) are present in the range of Lost River sucker and are suspected to compete and prey on them (FWS 2013). Management priorities in Oregon concentrate on aquatic nuisance species, which are the species whose current or potential impacts on native species and habitats and economic and recreational activity in Oregon are known to be significant (Hanson and Sytsma 2001). Some of the major potential freshwater invasive species are Chytrid fungus and mussels, including the zebra and quagga mussels (*Dreissena polymorpha*, and *Dreissena rostriformis bugenisis*).

Aquatic nuisance species could potentially be introduced into Pipeline project area waters by interbasin transfer of hydrostatic testing water or by being carried on equipment that is moved from outside of the region or between basins. PCGP has developed BMPs and guidelines to avoid the potential spread of aquatic invasive species (see *Hydrostatic Testing Plan* in appendix U) in consultation with the BLM and Forest Service as well as with ODEQ and the Center for Lakes and Reservoirs and Aquatic Bioinvasion Research and Policy Institute (Portland State University).

If determined to be feasible, all water used in hydrostatic testing would be returned to its withdrawal source location after use; however, cascading water from one test section to another to minimize water withdrawal requirements may make it impractical to release water within the same watershed where the water was withdrawn. If it is not possible to return the water to the same hydrologic basin from which it was withdrawn, PCGP would employ an effective and practical water treatment method (chlorination, screening/filtration, or other appropriate method) to disinfect the water that would be transferred across basin boundaries. The hydrostatic test water would be treated after it is withdrawn and prior to hydrostatic testing.

PCGP would implement a three-step BMP treatment process to prevent the potential spread of invasive species and forest pathogens from non-municipal surface water sources used during hydrostatic testing. The hydrostatic test water treatment process would incorporate screening/filtration during water withdrawal, chlorine treatment, and upland discharge at least 150 feet from wetlands or waterbodies with no direct discharge to these features. All hydrostatic test water would be released through a dewatering device such as a straw bale structure or sediment bag, in a manner to promote infiltration. Further, all hydrostatic release locations would be monitored after construction to ensure noxious weeds have not established.

As explained in the *Hydrostatic Testing Plan*, PCGP proposes to use a treatment of 2 ppm or 2 mg/L of free chlorine residual with a detention time of 30 minutes to treat all non-municipal surface waters that would be used as a water source for hydrostatic testing purposes. Chlorinated water would be released according to the Oregon Department of Environmental Quality criteria to prevent water quality impacts, potential effects to aquatic species, and minimize potential impacts to sensitive areas.

The potential for dispersal of aquatic nuisance organisms by other construction equipment and vehicles from one basin to another is remote. The BMPs in the noxious weed control procedures outlined in the ECRP (see appendix F) and the Integrated Pest Management Plan (see appendix N to the POD) would be employed to prevent the introduction and spread of invasive species from construction. With the implementation of these noxious weed control measures, introduction of nonnative species or movement of species between basins should not occur, resulting in no adverse effects to the listed Lost River sucker.

Fuel and Chemical Spills

Fisheries habitats could be adversely affected if petroleum products were accidentally discharged into aquatic environments including waterbodies crossed by dry open-cut (the Lost River and 31 ditches) with known or potential species presence that are included in table 3.5.5-2. Such materials are toxic to algae, invertebrates, and fish. Of the products likely to be present during construction, data compiled from a wide range of sources indicate that diesel fuels and lubricating oils are considerably more toxic to aquatic organisms than other, more volatile products (gasoline) or heavier crude oil (Markarian et al. 1994). For example, one study reported that release of diesel fuel in freshwater habitats significantly reduced aquatic invertebrate densities and species richness at least three miles downstream but invertebrate densities recovered within a year (Lytle and Peckarsky 2001). Impacts to aquatic habitats that primarily affect aquatic substrates—hence spawning, incubating and rearing habitats—can remain for much longer periods (Markarian et al. 1994).

Equipment used for construction across waterbodies could potentially release hydraulic fluid comprised of a variety of compounds, the most common of which are mineral oil-based, organophosphate esters, and polyalphaolefins (HHS 1997). Release from machinery can occur through faulty seals, hoses, sumps, and reservoirs, or general system failure.

Inadvertent spills of fluids used during construction, such as fuels and lubricants, could contaminate wetland soils and vegetation if not sufficiently contained. To minimize the potential for spills and any impacts from such spills, PCGP's SPCCP (see appendix L) would be implemented. In general, hazardous materials, chemicals, fuels, lubricating oils, and concrete-coating activities would not be stored, nor would refueling operations be conducted, within 100 feet (150 feet on BLM and NFS lands) of a wetland or waterbody in accordance with FERC's *Procedures* (see appendix C) and the SPCCP (see appendix L) except where no reasonable location is possible and additional containment steps have been taken. The SPCCP would be updated with site-specific information prior to construction. Adherence to these plans and procedures would result in effects to the listed Lost River sucker that would be unsubstantial.

Runoff from Facility Surfaces

There are nine contractor and pipe storage yards, one rock source and disposal site, two new temporary access roads, two new permanent access roads, and three aboveground facilities, including the Klamath Compressor Station, within the range of Lost River suckers.

Two of the yards, K-Falls Memorial Dr 1 Yard and K-Falls Memorial Dr 2 / Bair Yard, border the Klamath River, and the K-Falls - Industrial Oil Yard is about 235 feet from the Klamath River which is designated critical habitat for Lost River suckers. The Klamath Compressor Station is about 700 feet from the T Canal for which there are no records of Lost River sucker being present (construction and operation of the compressor station would not affect suckers even if present).

Stored materials at the yards may include: construction mats, fencing materials, fuel and lubricants, stormwater control materials (straw bales, erosion control fabric, silt fence materials, etc.), and other construction materials. The yards would also be used for contractor office trailers and employee parking facilities. Although the yards are previously disturbed industrial sites, stored materials and surface runoff could enter Lost River sucker critical habitat. Runoff from any of these sites would be mitigated through measures provided in PCGP's ECRP (see appendix F).

Operation and Maintenance Activities

Once installed, maintenance of the pipeline would include activities such as aerial inspections, gas flow monitoring, visual inspection of surrounding vegetation for signs of leaks, and integrity management, which includes smart pigging to investigate the interior surface of the pipe for any signs of stress cracking, pitting, and other anomalies (see the ECRP, appendix F). All of the proposed maintenance activities would be outlined in the Operations and Maintenance Plan that would be prepared according to operating regulations in DOT 49 CFR Subpart L, Part 192 and would be completed prior to the Pipeline going in-service. These general maintenance activities would require only surface activities and usage of the existing right-of-way, such as insertion of the pig at one of the pig launching facilities.

The potential stream channel disturbance would occur if an integrity issue with the pipeline were found at a crossing location. If this were to occur, the pipeline would need to be unearthed within the right-of-way and repair work done in-water. Within stream sites, repair work could require isolated flow from the section of pipe that is to be exposed. Typically, repairs would be made to the pipe within the right-of-way (within the trench) or, depending on the site-specific conditions and nature of the repair needed, a reroute around the affected section may be considered.

Impacts would be similar to those discussed above for initial installation except on a much smaller scale, because they would only involve one crossing compared to many crossings. However should repairs be needed out of the standard stream crossing window (i.e., during periods of fish spawning or egg incubation) there would be additional adverse effects to key fish resources at the specific site. The actions would include all relevant BMPs and mitigation, dependent upon site conditions and land ownership. Any future repairs would require additional permit approval from appropriate state and federal agencies which would determine the acceptable parameters of these actions. Such pipeline integrity-based in-water projects are very infrequent.

Vegetation maintenance would be limited adjacent to waterbodies to allow a riparian strip to permanently revegetate with native plant species across the entire right-of-way. To facilitate periodic pipeline corrosion/leak surveys, a corridor centered on the pipeline and up to 10 feet wide would be maintained in an herbaceous state, with scrubs outside of this 10 foot corridor. In addition, trees that are located within 15 feet of the pipeline may be cut and removed from the right-of-way. No vegetation or tree limitations would occur beyond the 30 foot wide corridor in riparian areas (i.e., up to 100 feet of streams on federal lands, and up to 25 feet of streams on non-federal lands). Since most native riparian vegetation along the Pipeline route has been altered by agriculture, the effects of maintaining the 30-foot wide corridor on Lost River sucker instream habitat would be minimal.

Herbicide Application

Herbicides have the potential to cause toxic effects to different sucker life stages and to other aquatic species, causing direct impacts, if used improperly. When herbicides are properly used according to label restrictions and BMPs to control noxious weeds, there is little to no chance of causing injury or mortality to fish or other aquatic organisms.

PCGP would not use herbicides for routine vegetation maintenance. However, following construction, PCGP would implement an Integrated Pest Management Plan (IPM - appendix N to PCGP's POD) that addresses control of noxious weeds and invasive plants across the Pipeline project which would include the selective use of herbicides where necessary to control noxious weeds by limited application from the ground, where allowed by landowners. The Integrated Pest Management Plan was developed in consultation with the ODA, BLM, and Forest Service. The BMPs would minimize the potential spread of invasive species and minimize the potential adverse effects of control treatments. Herbicides would not be applied by aerial or broadcast spraying. Noxious weeds would be removed only by manual methods in the riparian zone adjacent to streams, ditches and canals within the range of Lost River suckers. PCGP would not directly spray, or otherwise apply, herbicides in waterbodies or in riparian zones. The risk of drift would be avoided by selectively applying herbicides from the ground.

Where weed control is necessary along the construction right-of-way, PCGP's first priority would be to employ hand and mechanical methods (pulling, mowing, biological, disking, etc.) applicable to the species to prevent the spread of potential weed infestations, where feasible. To determine if an herbicide is to be used over other control methods, PCGP would base the decision on weed characteristics and integrated weed management principles (Forest Service 2005). If herbicides are used to control noxious weed infestations, they would be used when they are the most appropriate treatment method. Spot treatments and the use of selective herbicides would be utilized to minimize impact to native or non-target species. Permits or approvals for the use of herbicides and adjuvants on federal lands would be obtained prior to use/treatment, as detailed in the IPM (see appendix N to the POD, available upon request). Considering the potential for limited use of herbicides along the route and precautions that would be in place to prevent entry into waters, meaningful negative effects to the Lost River sucker from herbicides would be unlikely to occur.

Cumulative Effects

Within the action area, 100 percent of all lands are non-federal within the John C. Boyle Reservoir-Klamath River watershed, 99 percent are non-federal lands within the Lake Ewauna-Klamath River watershed, and 94 percent are non-federal lands within the Mills Creek-Lost River watershed. Degradation of water quality due to livestock grazing, agriculture, and timber harvest has resulted in severe pollution in Upper Klamath Lake. That in turn has led to algal blooms with increased mortality of suckers when oxygen depletions occur due to eutrophication particularly during summers when high temperatures combine with nutrient loading from pumping diked wetlands and runoff from farms. Past actions that have led to increased mortality have been due to private enterprise on private lands. Cumulative impact to Lost River suckers would include those same or similar actions which are reasonably foreseeable during the next 4 years. Cumulative impact from non-federal actions on non-federal lands are ongoing and will continue into the future. The effect from the construction and operation of the Project is anticipated to be temporary and localized and would not measurably contribute to the current or future cumulative effects upon this species.

Critical Habitat

Designated critical habitat for the Lost River sucker within the Pipeline project area is present only at the Klamath River crossing. The Pipeline would cross the Klamath River at RM 249, which is within critical habitat Unit 1, Klamath County (FWS 2012g). Unit 1 includes Upper Klamath Lake and Agency Lake, together with some wetland habitat; portions of the Williamson and Sprague Rivers; Link River; Lake Ewauna; and the Klamath River from the outlet of Lake Ewauna downstream to Keno Dam. Some or all of the three PCEs noted above (water, spawning and rearing habitat, and food) could be affected during the HDD across the Klamath River if an inadvertent return occurred with release of bentonite into the water column; the same effects to critical habitat that were described as Direct and Indirect Effects, above, would occur.

Only 0.04 acre within the Klamath River riparian zone (extending 117 feet or one site-potential tree height from each river bank) would be affected by construction, and all of that area is in an existing industrial facility.

3.5.5.4 Conservation Measures

Conservation measures have been proposed by PCGP to minimize construction and operation impact to waterbodies and riparian zones. Those measures have been compiled in table 2C in appendix N and apply to Lost River suckers.

PCGP has also proposed measures to rectify, repair, and rehabilitate and otherwise reduce impact to waterbodies and riparian zones once construction of the Pipeline is complete. Those measures have been compiled in table 3C in appendix N.

Details of some of the major conservation measures to be implemented by PCGP are summarized below.

Erosion Control

Many of the conservation measures in table 3C in appendix N focus on erosion control to prevent sediment from entering surface waters. Temporary erosion controls would be installed immediately after vegetation clearing and grading and would be properly maintained throughout construction and reinstalled as necessary until replaced by permanent erosion controls or restoration is complete. At a minimum, the following temporary erosion control structures would be installed: temporary slope breakers, sediment barriers, mulch, and erosion control fabric. PCGP would install permanent slope breakers consistent with the requirements of FERC's *Plan*. Part of long-term erosion control would include a final cleanup including final grading and installation of permanent erosion control structures. Final cleanup of an area would generally occur within 10 days after backfilling the trench and not be delayed beyond the end of the next recommended seeding season. During final cleanup, PCGP would remove all construction debris and grade disturbed areas to preconstruction grades to the extent practicable. An adequate seedbed would be prepared at the conclusion of cleanup.

Temporary Slope Breakers

PCGP would install temporary slope breakers over the backfilled, recontoured construction right-of-way as specified in FERC's *Plan*. The outfall of each temporary slope breaker would be to a stable, well-vegetated area or to an energy-dissipating device at the end of the slope breaker off the construction right-of-way. Slope breakers reduce runoff velocity, thereby intercepting sediment and allowing it to drop out of suspension. They also can effectively divert runoff away from a disturbed site to a stable outlet (Goldman et al. 1986).

Sediment Barriers

PCGP would primarily rely upon silt fence and staked hay or straw bales to confine sediment to the construction right-of-way. These structures would be used adjacent to wetland and waterbody crossings consistent with the requirements of FERC's *Procedures*. Straw bales and filter fabric (silt fence) can be used together to create a highly effective sediment barrier, a combination that compensates for the limitations of each used in isolation; straw bales provide extra support and the fabric provides greater filtering capability (Goldman et al. 1986).

All straw or hay bales used for sediment barriers would be certified as weed-free. Temporary sediment barriers would be maintained in-place until permanent revegetation measures are successful or until the upland areas adjacent to wetlands, waterbodies or roads are stabilized. The structures would be removed once vegetation in the area has been successfully restored.

Erosion Control Fabric

PCGP would install erosion control fabric (such as jute or excelsior) on waterbody banks at the time of recontouring. The fabric would be anchored using staples or other appropriate devices. Although there are no measures specific to pipeline construction, data related to cut-and-fill slopes treated during construction of forest roads indicate varying effectiveness of different types of stabilization measures designed to control surface erosion (EPA 2001). On fill slopes, combining straw mulch and netting decreased erosion by 99 percent. Excelsior mulch alone decreased erosion by 92 percent on fill slopes. On cut slopes, straw mulch by itself decreased erosion in a range from 32 to 97 percent (EPA 2001). Applications of mulches and/or fabric are effective measures promoting slope stabilization until vegetation can successfully be reestablished. These measures also promote plant growth (EPA 2001).

Fish Salvage Plan

Lost River suckers can potentially occur within the construction right-of-way on the Lost River at the time of construction. Since the Lost River would be crossed using dry open-cut technology, fish salvage procedures (see section 3.5.3.4 in coho salmon SONCC ESU) may occur while fish, including Lost River suckers, are within isolated construction sites. Since suckers in general appear to be vulnerable to electroshocking, PCGP's fish salvage plan in the Lost River may have to avoid use of electroshock, relying instead on seining and dip netting as described in section 3.5.3.4.

A *Fish Salvage Plan* has been provided in appendix T. The plan has been developed to minimize adverse effects to listed salmonids (SONCC coho, Oregon Coast coho), non-listed salmonids (Chinook salmon, steelhead, and cutthroat trout) and listed catostomids (Lost River sucker, shortnose sucker). The portions of the plan relevant to salvaging salmonids were adapted from the protocol developed by WSDOT (2011b). The protocol specifies procedures for 1) isolating the work area, 2) removing fish and dewatering the work area, 3) handling, holding, and releasing fish, 4) documenting fish that have been captured, handled, held, and released, and 5) notifying NMFS and FWS. The same protocol would generally be followed during salvage of Klamath Basin suckers. However, salvage operations within the crossing where these suckers may be present would include the latest *Handling Guidelines for Klamath Basin Suckers* (Reclamation 2008). These guidelines may be updated frequently. Some of the main factors in handling are the requirement of having a 0.5 percent saline solution of un-chlorinated well water to place any captured listed sucker in should it be collected during fish salvage operations. Aeration would also be supplied and the container a sucker is placed into would have been coated with a commercially available slime coat. Fish would be retained in this solution until released upstream of the capture site unless otherwise indicated through agreement with FWS.

OHV Barriers

Limiting OHV access would reduce potential increased sedimentation to streams and human access to sensitive fish areas. In accordance with FERC's *Plan*, the applicant must offer to install and maintain measures to control unauthorized vehicle access to the right-of-way to each landowner or manager of forested lands. Such measures may include signs; fences with locking gates; slash and timber barriers, pipe barriers, or a line of boulders across the right of way; and conifers or other appropriate trees or shrubs across the right-of-way. If allowed by the landowner, and if available, slash, stumps, and/or logs would be placed on the right-of-way within the riparian zones to discourage OHV crossings of streams and to provide carbon and nutrients. If not allowed, PCGP would discuss with the landowner the use of other methods, as noted above. At a minimum, the area would be revegetated and re-seeded.

Streambank Stability

The root network of trees adjacent to streambanks is essential to maintaining streambank stability (WDNR 1997). Because root strength decreases significantly at distances beyond one-half the tree crown diameter, trees promoting streambank stability lie within half a tree crown diameter from the streambank. Trees within 25 feet of the streambank are assumed to promote streambank stability (WDNR 1997). Generally, trees that must be removed during construction would be cut at ground level with the roots left in place, except where located within the trenchline. Although roots would decay overtime, streambank stability would be retained by their presence until revegetation is successful.

Streambank Restoration

PCGP's ECRP (see appendix F) describes the measures that would be used to stabilize streambanks crossed by the Pipeline. PCGP would not use riprap to stabilize streambanks. The alignment has been designed at waterbody crossings to be as perpendicular to the axis of the waterbody channel as engineering and routing constraints allow, minimizing streambank disturbance and avoiding parallel stream alignments or multiple stream crossings. Immediately after installation of a waterbody crossing, the contours of the streambed, shoreline, and streambanks would be restored to preconstruction configurations (i.e., contour/elevations) to restore the physical integrity/condition of these features and to minimize the loss of stream complexity.

PCGP has completed a scour analysis for the Pipeline project that would be used to ensure that appropriate pipeline burial depths and cover design parameters beneath channel streambeds and within adjacent floodplains are utilized, so that the effects on natural stream processes would be avoided or minimized. The Pipeline's scour analysis, which was completed by GeoEngineers, was included in PCGP's September 2017 FERC certificate application.

PCGP would install erosion control fabric (such as jute or excelsior) on streambanks at the time of recontouring. The fabric would be anchored using staples or other appropriate devices. The erosion control fabric to be used on streambanks would be designed for the proposed use and would be approved by PCGP's environmental inspectors (EIs).

Consistent with the FERC's *Procedures* (section V.C.3.), during streambank restoration/recontouring, the streambanks would be returned to their preconstruction contours or to a stable configuration. The Lost River is included in the application of the conservation measure. Streambank revegetation measures, including supplemental riparian planting procedures are also outlined in the ECRP. The shrubs and trees planted at each site would be determined at the time of planting based on the moisture regimes and site-specific conditions at each planting location and landowner requirements.

In-stream Gravel

Pipeline trenches across the Lost River and other perennial waterbodies within the Upper Klamath River Subbasin and Lost River Subbasin would be backfilled with material removed from the trench with the upper one foot of the trench backfilled with clean gravel or native cobbles of a size appropriate for resident fish, including suckers. The bottom and banks would be returned to preconstruction contours, banks would be stabilized, and temporary sediment barriers would be installed before returning flow to the waterbody channel.

Stream Crossing Risk Matrix

The FWS expressed concerns that more detailed site-specific information on bank material, streambed composition, shoreline vegetation, and other information is needed to adequately ensure that actions occurring at a stream crossing do not significantly increase streambank erosion and streambed instability. Follow-up surveys, site designs, and additional site actions resulting from these surveys as described below would reduce risk of stream bank and bed instability in Lost River sucker habitat to unsubstantial adverse effects levels.

PCGP, in response to these requests, has conducted an assessment of crossing conditions of all streams suitable for analysis based on the FWS risk matrix (GeoEngineers 2017d, 2017e, and 2018a). GeoEngineers, using a combination of field and GIS data, rated proposed stream crossings based on the matrix along the entire route including 19 stream, ditch, and canal crossings in the range of Lost River sucker. The matrix has two axes rating the crossing based on the impact potential at the crossing and the relative stream response potential at the crossing. Each crossing was rated as low, medium, or high for each of the two axes (all stream crossings were placed into one of nine categories, such as Low–Low, Low–Medium, and Medium–High).

No crossing within the range of Lost River sucker was rated as having both high risk of Pipeline project impact potential (i.e., high risk of impacts and high risk of site response potential) and high risk of stream and site response potential. For any crossing in this category, PCGP would develop a site-specific crossing plan, similar to that required by FERC for stream crossings over 100 feet wide. All crossings that would have an open cut within the range of the Lost River sucker had moderate or low ratings for the two categories. The Lost River crossing was rated moderate project impact potential and high for the relative stream response potential.

Those stream crossings that were rated to have a low or moderate project impact potential would be crossed using project-typical BMPs. The remaining stream crossings would have a variety of site-specific BMP actions taken to reduce the probability of stream bank and bed erosion or instability from project actions (see pre-construction surveys below). Stream crossings that are unstable can ultimately adversely affect aquatic resources from such factors as loss of local habitat, impacts to downstream habitat from addition of high unstable sediment, and increased recovery time of the specific site to stable conditions.

A pre-construction survey would be conducted by a technically qualified team on all stream crossings to confirm and clarify conditions developed in the aforementioned matrix analysis. This team would be composed of professionals qualified to assess terrestrial and aquatic habitat and the geotechnical and geomorphic conditions relative to pipeline construction across stream channels and ditches. Following these surveys, if significant changes were to occur to parameters of the risk matrix for a crossing, changes would be made to risk level and appropriate final methods of crossing and BMPs made at each stream crossing. If any crossing is moved into the "high" project impact and "high" stream response risk matrix category, a site-specific crossing design would be developed for that site. Construction would then move forward as described in permit documents including implementation of special additional BMPs, as described in GeoEngineers (2017d, 2017e, and 2018a), depending on individual site conditions. Special additional BMPs may include such actions as changes in bank material and bank angle, specific substrate composition used, plants used on the bank, artificial stabilizing bank material, rootwad enhancement, and various other actions.

As a follow-up measure to help ensure crossing actions would not adversely affect stream bank and channel structure, PCGP would monitor stream crossings to ensure long-term success of the restoration, maintenance of fish passage, and to identify channel erosion, scour or migration that could destabilize the site or expose the pipeline. As requested by FERC, PCGP developed a monitoring plan (GeoEngineers 2017e, 2018a) following consultation with a representative from FWS and NMFS (Castro 2015). The monitoring plan would be customized, where necessary, to address risks of stream crossings identified in the Risk Analysis and those identified in subsequent preconstruction surveys.

Monitoring would consist of:

- Annual visits to all stream crossings, regardless of risk level, as part of PCGP's monitoring of pipeline integrity. These visits would be completed by PCGP staff and would note any obvious signs of channel erosion, pipeline exposure, or major shifts in restoration elements. Potential problem areas would be subsequently visited by PCGP and a geoprofessional.
- Aerial reconnaissance would be completed annually for the life of the Pipeline and stream crossings would be reviewed for major landscape changes such as channel migration and excessive erosion. Potential problem areas would be subsequently visited by PCGP and a geoprofessional.
- Quarterly site visits to all sites in the Orange management category (see GeoEngineers 2018a) for 2 years post construction to monitor revegetation success, structural stability of the restoration elements, any changes to fish passage potential resulting from the Pipeline, evidence of channel migration, erosion, head-cutting, or other stream channel movement that could influence stream or pipeline stability. Field measurements would be taken to monitor adjustments to the channel profile and cross sectional area.
- Annual site visits to 15 percent of all sites in the Blue management category and 100 percent of all sites in the Yellow management category (see GeoEngineers 2018a) for 2 years post construction to monitor revegetation success, structural stability of the restoration elements, any changes to fish passage potential resulting from the Pipeline, evidence of channel migration, erosion, head-cutting, or other stream channel movement that could influence stream or pipeline stability. Field measurements would be taken to monitor adjustments to the channel profile and cross-sectional area.
- Annual site visits to 50 percent of the sites in the Yellow and 100 percent of sites in the Orange management category (see GeoEngineers 2018a) by a geo-professional in Years 3, 5, 7, and 10 to monitor revegetation success, structural stability of the restoration elements, any changes to fish passage potential resulting from the Pipeline project, evidence of channel migration, erosion, head-cutting, or other stream channel movement that could influence stream or pipeline stability. Field measurements would be taken to monitor adjustments to the channel profile and cross-sectional area.

- Observations would be made during all site visits on the effects of cattle/elk browsing on restoration success, and of impacts associated with recreational use.
- Revegetation planning along the right-of-way is detailed in the ECRP. The ECRP describes monitoring and performance standards for revegetation.
- Records would be maintained annually to document any significant hydrologic events (flow or rainfall) that occur in between site visits. This shall be done to better understand the site response to moderate or large flood events. As gauging stations are extremely limited over the majority of the crossings along the Pipeline route, rainfall records would be used to identify the potential flooding that may occur in between scheduled monitoring events. These climatic events would be considered during annual monitoring when evaluating site response.
- Unscheduled site visits may be completed at stream crossings on BLM and USFS jurisdiction following localized rainfall events exceeding a 25-year rainfall intensity to monitor revegetation success, structural stability of the restoration elements, any changes to fish passage potential resulting from the Pipeline, evidence of channel migration, erosion, head-cutting, or other stream channel movement that could influence stream or pipeline stability. Field measurements would be taken to monitor adjustments to the channel profile and cross-sectional area.
- Annual reporting in Years 1, 2, 3, 5, 7, and 10 following construction would be provided to outline observations of stream crossings and any remedial action taken to restore site conditions.
- Monitoring frequency and locations may be modified in response to demonstrating site restoration success in the Annual Monitoring reports

Overall, these actions would reduce potential adverse effects from bank and bed stability to the listed Lost River sucker to unsubstantial levels.

3.5.5.5 Determination of Effects

Species

The Pipeline project **may affect** Lost River suckers because:

- Lost River suckers occur within the Upper Klamath and Lost River Subbasins, which would be affected during construction of the proposed action.

While several Pipeline project actions are not likely to cause adverse effects, those resulting effects from Pipeline project components that are **likely to adversely affect** Lost River suckers include:

- Lost River suckers could occur in 19 waterbodies crossed by dry open-cut construction in the Lake Ewauna-Klamath River watershed and in 13 waterbodies west of MP 214.38 (including the Lost River) crossed in the Mills Creek-Lost River watershed and be indirectly affected by elevated suspended sediment levels, streambank erosion and stability, and aquatic nuisance species introductions; and
- adults and juveniles subject to fish salvage within the isolated construction sites at 31 ditches crossed by dry-open cuts and the Lost River could be affected if electroshocking is used and stressed if seining is used.

Critical Habitat

The Pipeline project is **not likely to adversely affect** designated critical habitat for the Lost River sucker because:

- HDD would avoid critical habitat in the Klamath River.

3.5.6 Shortnose Sucker

3.5.6.1 Species Account and Critical Habitat

Status

The shortnose sucker was listed as a federally endangered species on July 18, 1988 (FWS 1988). The shortnose sucker was listed as endangered because of the loss of habitat and access to historical range, resulting in a declining population. A five-year review was released in August 2013 recommending no change to the current listing status as endangered (FWS 2013o).

Threats

Lost River suckers and shortnose suckers were considered together in the final rule listing both as endangered species. Numerous factors in both species' decline were cited by FWS (1988) including historical over-fishing, dams limiting upstream movements and access to spawning habitats, introduction of non-native species that compete (fathead minnows) and prey on suckers (yellow perch, bullheads, largemouth bass, and various lepomid sunfish), and degradation of water quality due to livestock grazing, agriculture, and timber harvest. Pollution in Upper Klamath Lake has led to algal blooms with increased mortality of suckers when oxygen depletions occur due to eutrophication. Status assessments conducted in 2001 and 2002 (FWS 2002a) concluded that the shortnose sucker was threatened by the following: 1) drastically reduced adult populations and reduced range; 2) extensive habitat loss, degradation, and fragmentation; 3) small or isolated adult populations as a result of dams; 4) poor water quality; 5) lack of sufficient recruitment; 6) entrainment into irrigation and hydropower diversions; 7) hybridization with the other native Klamath sucker species; 8) potential competition with introduced exotic fishes; and 9) lack of regulatory protection.

Many of these same issues remained as factors threatening the species' recovery in 2013 (FWS 2013l). Regulatory protection of aquatic habitats inhabited by shortnose suckers has improved with implementation of various state (Oregon and California) and federal laws that minimize effects of actions on the species and habitat during project planning and consultation. However, shortnose suckers continue to be affected by adverse water quality, habitat degradation, toxicity from blue-green algae, and entrainment into irrigation and hydropower diversions. Added to the earlier threats listed is climate change which is predicted to increase flows during winter months but decrease flows during the spawning period, from March or mid-April through May (FWS 2013l).

Approximately 400 habitat restoration projects have been completed or are planned for the Upper Klamath Lake Basin to help offset historical habitat loss. Shortnose suckers have been observed using the 6,000-acre habitat area of Williamson River Delta to Upper Klamath Lake where restoration has occurred. Additionally, the Chiloquin Dam on the Sprague River in 2008 was removed, which unblocked 75 miles of stream believed to be migration and spawning habitat. Because these efforts are so recent, population-level effects have not yet been observed. However, these actions and others are believed to be significant toward the improved status of this species (FWS 2013l). Nevertheless, poor water quality in Upper Klamath Lake and the Lost River continues to threaten the viability of the species. The water quality issues are most pronounced during summers when high temperatures combined with nutrient loading from pumping diked wetlands and runoff from farms, roads, and other sources cause detrimental water quality for fish species. Also, lake sediments create hypereutrophic conditions which lead to depletions of dissolved oxygen and fish die-offs (FWS 2007f, 2013l). A cyanobacterium, now present in Upper Klamath Lake, undergoes massive algal blooms; photosynthesis during daylight can supersaturate water with dissolved oxygen and respiration at night can deplete dissolved oxygen with both events deleterious to shortnose suckers (FWS 2013l). Blue-green algal or cyanobacter toxins (Microcystin) have recently been found to affect liver, intestines, kidneys, heart, spleen, and gills of suckers (FWS 2013l).

Population levels were estimated to be about 2,700 individuals in 1984 prior to listing. Although this estimate is likely inaccurate, it was substantially lower than historic population levels (FWS 2013l). This decrease in abundance was due to the following factors: habitat loss of approximately 77 percent of historic range, restricted access to spawning habitat, overharvest, and increased rates of mortality resulting from entrainment in water management structures and severely impaired water quality (FWS 2007f, 2013l). Population levels in Upper Klamath Basin are not well known, but production is affected by lack of suitable spawning habitat and spawning success. The Tule Lake population has better survival conditions than that of the Upper Klamath Lake system primarily due to better water quality. Length-frequency analysis suggests that the last substantial recruitment to the spawning population occurred during the late 1990s (FWS 2012f).

Species Recovery

Actions described in the recovery plan that would aid in the delisting of the shortnose sucker include improving habitat conditions through rehabilitating riparian areas and improving land management practices in the Klamath Basin watershed, developing and achieving water quality and quantity goals, and improving fish passage, spawning habitat, and other habitat conditions.

A recovery plan for Lost River sucker and shortnose sucker was finalized on March 17, 1993 (FWS 1993b). Since then additional information prompted revision of the recovery plan (FWS 2012f). The recovery program goal is to stop the population decline and enhance Lost River sucker and shortnose sucker populations so that ESA protection is no longer necessary.

At the time of listing, population declines were related to loss or degradation of spawning, rearing, and adult habitats. Only about 25 percent of the original habitat remains. Reductions in habitat quality compound the effects of reduced habitat quantity and availability on Lost River sucker and shortnose sucker abundance. In addition to habitat, factors currently limiting species recovery include high mortality of larvae and juveniles due to reduced rearing habitat, entrainment in water management structures, poor water quality, and adverse effects (predation, competition) from non-native, introduced fish species. Compounding effects from drought and water diversions affect lake water levels and unscreened water diversions and fish entrainment continue as threats. Substantial entrainment occurs at the river gates of the Link River Dam (FWS 2013l). Some of the shortnose suckers that pass through the gates pass downstream to the Keno Reservoir and farther along the Klamath River where they cannot return upstream. Nevertheless, there is a small population inhabiting Lake Ewauna, probably fish that survived passage through the Link River Dam and other hydroelectric canals and turbines (FWS 2013l).

Adult populations are limited by extremely low recruitment as well as by high levels of stress and mortality associated with severely impaired water quality. As a whole the species is potentially limited by the lack of habitat connectivity (FWS 2012f). However, one of the main passage barriers that reduced access to 95 percent of its river spawning habitat, the Chiloquin Dam on the Sprague River, was removed in 2008 (NMFS and FWS 2013).

Demographic-based objectives include increasing larval production, individual survival, and recruitment to spawning populations, and ultimately increasing abundance in spawning populations. The objectives of restoring spawning and nursery habitat, expanding reproduction, reducing the negative impacts from water quality on all life stages, clarifying the effects of other species on all life stages, reducing entrainment, and establishing auxiliary populations comprise the threats-based objectives. The recovery strategy is intended to produce and document healthy, self-sustaining populations by reducing mortality, restoring habitat (including spawning, larval, and juvenile habitats), and increasing connectivity between spawning and rearing habitats. It also involves ameliorating adverse effects of degraded water quality, disease, and non-native fish. The plan provides areas of emphasis and guidelines to direct recovery actions (FWS 2012f).

There are two recovery units for shortnose suckers, the Upper Klamath Lake Unit and Lost River Basin Unit (FWS 2012f). Upper Klamath Lake Unit includes all shortnose suckers within the lake, tributaries to Upper Klamath Lake, and reservoirs within the Klamath River including Keno Reservoir and populations below Keno Reservoir. The Lost River Basin Unit includes Clear Lake Reservoir and tributaries including Willow Creek, Boles Creek, Tule Lake, Gerber Reservoir and tributaries, and the Lost River mainstem (FWS 2012f) even though the Lost River is not included in designated critical habitat. The Lost River proper includes individual suckers in the mainstem downstream from the Clear Lake Dam to Anderson-Rose Diversion Dam, including the Lost River tributary Miller Creek, downstream from Gerber Dam. The population in the Lost River drainage below Clear Lake Dam is comprised mostly of adults (FWS 2012f).

Life History, Habitat Requirements, and Distribution

Shortnose suckers are native to the Upper Klamath River Basin and Lost River Basin but have adapted to lake habitats and spawn in larger tributary rivers associated with lakes (Moyle 2002), generally from February through early May. Larval stages persist from May through July (Reclamation 2007). Although Lost River suckers may live to 43 years old, shortnose suckers are shorter-lived, surviving to 25 years old; females attain sexual maturity at 4 years old while Lost River sucker females are sexually mature at 6 to 9 years old (Reclamation 2007). Shortnose sucker females may produce 72,000 eggs per spawning season, generally fewer than Lost River suckers.

River spawning habitats include riffles or runs with gravel or cobble substrate, with moderate flows, and in water 4 to 51 inches deep. Shortnose suckers have historically spawned in lakes, particularly at springs occurring along the shorelines (FWS 2007f). Currently, shortnose suckers are found in Upper Klamath Lake and its tributaries, Klamath River downstream to Iron Gate Reservoir, Clear Lake Reservoir and its tributaries, Gerber Reservoir and its tributaries, the Lost River, and Tule Lake. In the Upper Klamath Lake watershed, shortnose sucker spawning runs are primarily limited to the Sprague and Williamson Rivers, although spawning runs may also be present in the Wood River and in Crooked Creek. Shortnose sucker spawning has also been recorded in the Clear Lake watershed (FWS 1988) and Gerber Reservoir watershed (FWS

1994a). Adult and juvenile shortnose suckers prefer turbid, highly productive but shallow lakes that are cool in the summer with adequate dissolved oxygen and water that is moderately alkaline (FWS 2007f).

As discussed for Lost River suckers, a small population of several hundred adult shortnose suckers exists in Tule Lake but, the population in the Lost River drainage below Clear Lake Dam is comprised mostly of adults, and the Lost River functions as a population sink with no likely chance of being self-sustaining because of low recruitment and lack of access to spawning habitats (FWS 2012f). Shortnose suckers have resident populations in both lake and some riverine habitats, including Lost River, Willow Creek, and other tributaries of Clear Lake and Gerber Reservoir (Reclamation 2007). Shortnose suckers have been documented spawning below Anderson-Rose Dam, in Big Springs near Bonanza, and at the terminal end of the West Canal as it spills into the Lost River. Suitable spawning habitats with riffle areas and rocky substrates include the spillway area below Malone Dam, immediately upstream of Keller Bridge, immediately below Big Springs in the Lost River, below Harpold Dam, and adjacent to Station 48 (Reclamation 2007). Seasonal movements of shortnose suckers are similar to those described for Lost River suckers.

Population Status

At the time of the Final Rule, estimates of the shortnose sucker population could not be made. Nevertheless, there was very little recruitment to the population and that, plus mortality from fish die-offs and fishing, indicated a declining trend (FWS 2007f). Continued efforts to estimate shortnose sucker populations have been based on several approaches which indicate a declining population with nearly no measurable recruitment in Upper Klamath Lake and limited survival of adults past the age of sexual maturity. Shortnose suckers attain sexual maturity when 4 to 6 years old and survival after entering the spawning population was estimated at only 3.6 years indicating insufficient time for reproduction to sustain the population (FWS 2007f).

For several years there was no indication that shortnose suckers continued to inhabit Tule Lake, but in 1991 both sucker species were observed spawning below Anderson-Rose Dam, and sampling at Tule Lake in the early 1990s determined that small populations of the two species were present (Reclamation 2007). Estimates of shortnose sucker annual survival rates in Upper Klamath Lake between 1995 and 2004 indicate that the population is likely to be decreasing, although the survival estimates appear to be imprecise (Reclamation 2007).

Shortnose sucker spring-spawning abundance in 2007 was estimated to be 42 percent and 48 percent of 2001 abundancies for males and females respectively (FWS 2012f). Tagging studies conducted on Lost River suckers and shortnose suckers in Gerber Reservoir and Clear Lake (both impoundments are connected to the Lost River below Gerber Dam and Clear Lake Dam, respectively) indicated that numbers of large adult suckers of both species had declined since 2000. Declines in large adult shortnose suckers have been particularly pronounced in Clear Lake Reservoir, possibly due to poor recruitment from younger age classes prior to 2000 (Barry et al. 2009).

Hewitt et al. (2015) estimated λ and other population demographic properties for the adult spawning population of shortnose suckers in Upper Klamath Lake from 2001 to 2012 (figure 3.5.6-1). In the figure, the population rate of change ($\lambda = N_{t+1} / N_t$) indicates positive or negative growth. When $\lambda > 1$, the rate of change is positive and the population (N) has grown from N_t to N_{t+1} in the next time interval. Alternatively, the population is stable when $\lambda = 1$, but when $\lambda < 1$, the population has declined from N_t to N_{t+1}. The data show a declining adult spawning population but does not indicate changes in the whole population because it does not account for changes in the numbers of juveniles from year to year. With additional demographic data, Hewitt et al. (2015) concluded that current spawning population is a subset of the individuals that were present in the late 1990s. Both male and female shortnose suckers appear to have reached senescence. Low estimates of survival from 2010 to 2012 may indicate increased mortality is occurring as a result of older age classes.

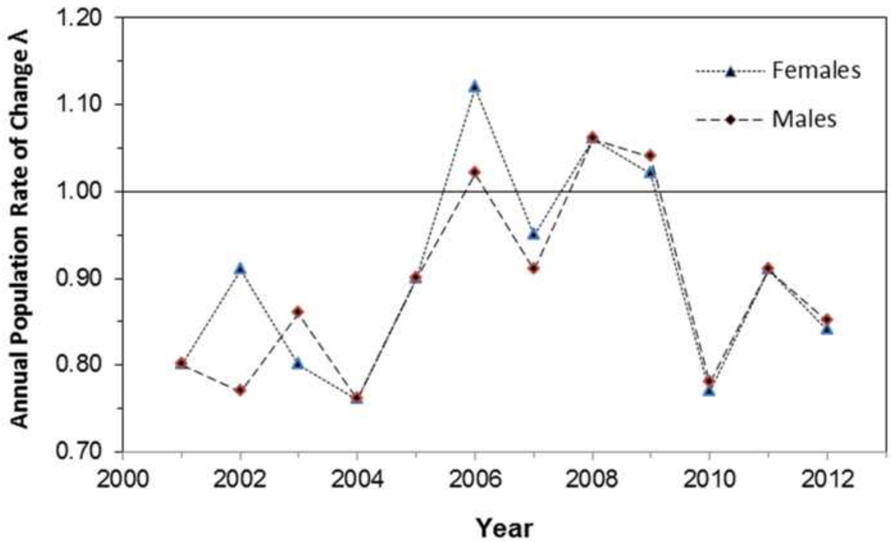

Figure 3.5.6-1. Estimates of Annual Population Rate of Change (λ) for Shortnose Suckers from the Spawning Population in Upper Klamath Lake, Oregon. The Population is declining when λ < 1 (data from Hewitt et al. 2015).

Critical Habitat

Critical habitat for the Lost River sucker and shortnose sucker was proposed by FWS in 1994 (FWS 1994a). Critical habitat for Lost River and shortnose suckers was re-proposed in 2011 and designated in 2012 (FWS 2012g). Along the route of the Pipeline, designated critical habitat for Lost River and shortnose sucker (Unit 1 in Klamath County) includes the Link River, Lake Ewauna, and the Klamath River downstream to Keno. Unit 2 in Klamath and Lake Counties, Oregon and Modoc County, California includes Clear Lake Reservoir and tributaries and Gerber Reservoir and tributaries, but does not include Tule Lake and its tributary, the Lost River. For reasons described above (blockage by Anderson-Rose Diversion Dam), neither Tule Lake or Lost River provides spawning habitats or supports viable self-sustaining populations of Lost River or shortnose suckers (FWS 2012g). The Pipeline does not coincide with critical habitat in Unit 2.

In Unit 1 (Upper Klamath Lake), there are 13 miles of critical habitat on federal land, less than 1 mile on state land, and 106 miles on lands of private/other ownership. In Unit 2 (Lost River Basin), there are 23 miles of critical habitat on federal land, less than 1 mile on state land, and 3 miles on lands of private/other ownership (FWS 2012g).

PCEs of critical habitat include (FWS 2012g):

1. Water. Areas with sufficient water quantity and depth within lakes, reservoirs, streams, marshes, springs, groundwater sources, and refugia habitats with minimal physical, biological, or chemical impediments to connectivity. Water must have varied depths to accommodate each life stage: shallow water (up to 3.28 ft [1.0 m]) for larval life stage and deeper water (up to 14.8 ft [4.5 m]) for older life stages. The water quality characteristics should include water temperatures of less than 82.4°F (28.0°C); pH less than 9.75; dissolved oxygen levels greater than 4.0 mg/l; low levels of microcystin; and un-ionized ammonia (less than 0.5 mg/l). Elements also include natural flow regimes that provide flows during the appropriate time of year or, if flows are controlled, minimal flow departure from a natural hydrograph.
2. Spawning and rearing habitat. Streams and shoreline springs with gravel and cobble substrate at depths typically less than 4.3 ft (1.3 m) with adequate stream velocity to allow spawning to occur. Areas containing emergent vegetation adjacent to open water provide habitat for rearing and facilitate growth and survival of suckers as well as protection from predation and protection from currents and turbulence.
3. Food. Areas that contain an abundant forage base, including a broad array of chironomidae, crustacea, and other aquatic macroinvertebrates.

3.5.6.2 Environmental Baseline

Analysis Area

For shortnose suckers, the riverine analysis area is limited to fresh waterbodies within the Upper Klamath Subbasin (HUC 18010206; see Lost River sucker figure 3.5.5-2A) and Lost Subbasin (HUC 18010204; see figure 3.5.5-2B). The riverine analysis area includes two components: 1) the water column and substrate of all waterbodies crossed by the Pipeline from the point of crossing to the extent downstream where water quality is adversely affected by turbidity generated during construction and sediment generated by runoff from the construction right-of-way; and 2) waterbodies' associated riparian zones affected in the short-term during construction and in the long-term by operation. The riverine analysis area for the shortnose sucker includes two perennial flowing river crossings (Klamath and Lost River) and 106 intermittent streams, ditches, and canals that would either be crossed or are in the right-of-way. The two perennial flowing rivers likely have shortnose suckers present. In addition to the 2 perennial waterbodies, the Pipeline will also cross 83 intermittent streams, ditches and canals; 23 additional intermittent streams, ditches, ponds and canals would be adjacent to the Pipeline, within the construction right-of-way, but not crossed. There is no information to indicate that shortnose suckers occur in any of these intermittent waterbodies but they are included in the riverine analysis area for shortnose suckers.

Species Presence

Shortnose suckers are found in Upper Klamath Lake and its tributaries, Klamath River downstream to Iron Gate Reservoir, in Clear Lake Reservoir and its tributaries, Gerber Reservoir and its tributaries, the Lost River, and Tule Lake (FWS 2013l). Shortnose sucker spawning has also been recorded in the Clear Lake watershed (FWS 1988) and Gerber Reservoir watershed (FWS 1994a). In the Upper Klamath Subbasin (HUC 18010206) shortnose sucker are found in the Klamath River as far downstream as Copco Reservoir and possibly Iron Gate Reservoir. In the Lost River Subbasin, they are found in the Lost River mainstem below Anderson-Rose Diversion Dam, above Malone Dam, and in Clear Lake Reservoir (Moyle 2002).

Shortnose suckers spawn in the Lost River and are present in John C. Boyle Reservoir, downstream from the pipeline crossing at RM 225 (NRC 2004). In addition to collections of shortnose suckers in John C. Boyle Reservoir, ORBIC (2012) cites records of spawning in the Link River. Shortnose suckers have been documented from Lake Ewauna and in the Lost River Diversion Canal. Currently, shortnose suckers migrate a short distance from Tule Lake to spawn in the Lost River below Anderson-Rose Diversion Dam (RM 17.4) south of Merrill and approximately 7.6 river miles from the pipeline crossing of the Lost River (ORBIC 2017b). Suckers also spawn in the Lost River below Malone Dam, downstream from Clear Lake Reservoir. A population inhabits the Tule Lake sumps at the terminus of the Lost River (FWS 2007f). That population is isolated from upstream spawning habitats in the Lost River by the Anderson-Rose Diversion Dam and the population is not self-sustaining (FWS 2007f). As of 2006, shortnose suckers had been documented in the Lost River from the confluence with Miller Creek to Tule Lake, a reach that coincides with the proposed pipeline crossing of the Lost River (FWS 2013l). Shortnose suckers continue to occupy the Lost River below Anderson-Rose Diversion Dam to Tule Lake (Hodge and Buettner 2009).

Within the Pipeline project area, the shortnose sucker has been documented within the Klamath River from Klamath Falls to Keno Reservoir. The Pipeline would cross the Klamath River at RM 249. The shortnose sucker is also known to be present from Tule Lake Sump and Clear Lake Reservoir in northern California, which are connected by the Lost River. Tule Lake Sump is at the lower terminus of the Lost River and the population in Tule Lake is isolated from upstream spawning areas by multiple dams including blockage by the Anderson-Rose Diversion Dam.

Historically, dewatering of canals, laterals, and drains has included biological monitoring and salvage of listed species, as needed. Canals, laterals, and drains are dewatered at the end of irrigation season which includes capture and relocation (salvage) of suckers from the canal system after dewatering occurs. Nearly all canals, laterals, and drains are either dewatered after the irrigation season, before April and after October, or have the water lowered for inspection and maintenance (NMFS and FWS 2013). Canals remain dewatered until the following spring (as early as late March) except for the input of localized precipitation-generated runoff (NMFS and FWS 2013). Reclamation’s fish salvage efforts focus on the A Canal forebay in front of the fish screen, C4 Canal, D1 Canal, and D3 Canal within the Klamath Irrigation District, and J Canal within the Tule Lake Irrigation District (NMFS and FWS 2013). The Pipeline would cross the C-4-E Lateral at MP 201.63, the C-4 Lateral at MP 204.12, the C-4-F Lateral at MP 204.33, and the C-4-C Lateral at MP 205.50 in the Lake Ewauna-Klamath River watershed. In addition, the Pipeline would cross the C Canal at MP 205.96 and the C-4-7 Lateral at MP 207.40 in the Mills Creek-Lost River watershed. All six canals and laterals are presumed to be associated with the C4 Canal and may be occupied by shortnose suckers prior to dewatering. The Pipeline would not cross the A Canal, D1 Canal, the D3 Canal, or the J Canal.

Past efforts have shown that salvage of suckers is practicable in some locations, but numbers of salvaged suckers are highly variable among years and sites (NMFS and FWS 2013). Occurrence of shortnose suckers in canals and ditches operated and maintained by Reclamation is possible if they are crossed before dewatering begins in October. However, based on the unpredictability of shortnose sucker occurrence at any one site at any specific time, there is no way to anticipate the species’ presence during construction.

All canals, laterals, and drains operated and maintained by Reclamation would be crossed using conventional bores, thus avoiding any instream construction and conflicts with shortnose suckers if present. Irrigation ditches and roadside ditches on private land would be crossed by dry open-cut construction if water is present at the time. The connectivity of those ditches with canals, laterals, and drains operated and maintained by Reclamation is unknown. Because of their small size and function as agricultural drains, shortnose suckers are not expected to occur. A total of 26 streams/ditches in the Lake Ewauna-Klamath River watershed and 59 streams/ditches in the Mills Creek-Lost River watershed would be crossed (85 total) by the Pipeline. The right-of-way would not cross but would be adjacent to 23 additional streams/ditches in the two watersheds. Altogether, the Pipeline would potentially affect 108 waterbodies in the range of the shortnose sucker included in table 3.5.5-1 (in Lost River sucker section 3.5.5). All but the Klamath River and Lost River have intermittent flow. There are 106 intermittent streams or ditches between MPs 188.9 and 228.1; 58 would be crossed by dry open cutting and 25 of them would be crossed using a conventional bore (with no instream construction). Twenty-three intermittent streams/ditches/canals would not be crossed but are present within the construction right-of-way (see table 3.5.5-1). They are also expected to be dry at the time of construction.

Habitat

The Lost River has been highly altered to meet the needs of agriculture and reduce the threat of flooding, and therefore habitat is fragmented and disconnected by dams lacking fish passage (NMFS and FWS 2013). Much of the water flowing through the lower Lost River channel comes from Upper Klamath Lake through the A Canal. Consequently, water in the Lost River is high in nutrients and is reused many times by different users causing nutrient concentrations to be increased. Water flowing in the Lost River eventually empties into the Tule Lake NWR as return flow from irrigation (no water is released through the Anderson-Rose Diversion Dam) and can be pumped to the Lower Klamath NWR before flowing to the Klamath River via the Klamath Straits Drain (NMFS and FWS 2013). The extensive alterations of the Lost River watershed, along with inputs from Upper Klamath Lake and agricultural drainage, have contributed to seasonally poor water quality and the Lost River is listed by the State of Oregon for exceedances in temperature, dissolved oxygen (DO), pH, algal biomass, and ammonia toxicity (NMFS and FWS 2013).

Dams continue to limit passage and sucker migration, impose isolation of subpopulations, and decrease available spawning habitats which raise the possibility of facilitating hybridization between several sucker species (Reclamation 2007). Dams may also cause stream channel changes, alter water quality, and provide habitat for exotic fish that prey on suckers or compete with them for food and habitat (Reclamation 2007). Although there are seven major dams in the Klamath Basin that may affect the migration patterns of listed suckers, only the Link River Dam has been recently equipped with a fish ladder that was designed specifically for sucker passage (Reclamation 2007). Fish ladders are present at John C. Boyle and Keno Dams and, although suckers have been observed to use the ladders, they were not designed for sucker passage and generally are inadequate for sucker passage (Reclamation 2007).

The Link River Dam regulates water flows downstream to Lake Euwana, Keno Reservoir, and the Klamath River. The river gates on the dam do not protect fish from becoming entrained and numerous juvenile suckers are drawn through the dam gates. Shortnose suckers that survive passing through the hydroelectric facilities either die due to poor summer water quality conditions or pass downstream into the Klamath Reservoir. At that point, fish cannot return and are believed to be lost from the breeding population (FWS 2007f).

Adverse water quality is the most critical threat to the shortnose sucker (FWS 2007f). Klamath River and Klamath Lake have been designated as water quality impaired, including for nutrient loads which are enhanced by drainage of irrigation water from agricultural lands adjacent to Klamath Lake. Construction of dikes and drainage systems converted wetlands to agricultural use. Soils high in organic content were subject to mineralization processes which released nutrients into the aquatic system, especially phosphorous and nitrogen (Rykbost and Charlton 2001).

High levels of phosphorous in Klamath Lake have led to extreme eutrophication events that promote algal blooms dominated by the blue-green algae *Aphanizomenon flos-aquae* that reach or nearly reach theoretical biological maxima (NRC 2004). As a consequence, portions of Upper Klamath Lake develop conditions of oxygen depletion or are anoxic, and accumulate high concentrations of ammonia, which has resulted in mass mortality of fish, including adult suckers (NRC 2004). Shortnose suckers are likely to experience high mortality if exposed to one or more of the following: pH 9.8 or higher, ammonia (unionized) concentration 0.34 mg/l or higher, water temperatures 29.4°C (≥85°F) or higher, and DO concentrations 2.3 mg/l or less (Bellerud and Saiki 1995). Seasonally low DO concentrations occur throughout the Lost River and can be especially low in reservoirs where concentrations < 2 mg/L have been reported as lasting from a day to several weeks in Anderson-Rose, Harpold, and Wilson Reservoirs, with DO concentrations near 0 mg/L observed in some reservoirs (NMFS and FWS 2013).

No assessments have been conducted for either of the two fifth-field watersheds that would be crossed by the Pipeline in the Lost Subbasin: Lake Ewauna-Klamath River (HUC 1801020412) and Mills Creek-Lost River (HUC 1801020409). Likewise, no stream reaches have been sampled under ODFW's Aquatic Inventories Project in either of the fifth-field watersheds. Nevertheless, modifications and degradation of aquatic habitats have been documented by FWS (1993b and 2012f), USGS (Dileanis et al. 1996), Reclamation (2007), and the NRC (2004), among others.

There are no recent long-term water discharge data for waterbodies in the Lost River watershed. The A Canal connects the Link River to the Lost River via the B Canal. According to USGS Gage 11507200, there is no flow in the A Canal between November and March (see figure 3.5.5-4, in section 3.5.5, Lost River sucker), consistent with periods of water diversions from the Klamath River, discussed above. Adequate flow and habitat conditions in the Lost River are likely during the spring and summer with higher river flows supplemented by releases from Clear Lake and Gerber reservoirs (NMFS and FWS 2013). Irrigation releases typically start in April. Flows in the Upper Lost River are very low during the fall and winter because flows from Clear Lake and Gerber reservoirs are considerably reduced, but winter flows do increase downstream from tributary and spring contributions (NMFS and FWS 2013).

Critical Habitat

Designated critical habitat for the shortnose sucker is present within the Pipeline project area. The Pipeline would cross the Klamath River at RM 249, which is within critical habitat Unit 1, Klamath County (FWS 2012g). Unit 1 includes Upper Klamath Lake and Agency Lake, together with some wetland habitat; portions of the Williamson and Sprague Rivers; Link River; Lake

Ewauna; and the Klamath River from the outlet of Lake Ewauna downstream to Keno Dam. PCEs include (FWS 2012g):

1. **Water.** Areas with sufficient water quantity and depth within lakes, reservoirs, streams, marshes, springs, groundwater sources, and refugia habitats with minimal physical, biological, or chemical impediments to connectivity.
2. **Spawning and rearing habitat.** Streams and shoreline springs with gravel and cobble substrate at depths typically less than 1.3 meters (4.3 feet) with adequate stream velocity to allow spawning to occur. Areas identified in PCE 1 containing emergent vegetation adjacent to open water, which provide habitat for rearing and for growth and survival of suckers.
3. **Food.** Areas that contain an abundant forage base, including a broad array of chironomidae, crustacea, and other aquatic macroinvertebrates.

Critical habitat Unit 2 includes Clear Lake Reservoir and its principal tributary, Willow Creek. Unit 2 does not coincide with the Pipeline project area.

3.5.6.3 Effects of the Proposed Action

In the riverine analysis area, only the Klamath River and the Lost River are inhabited by shortnose suckers based on available information (ORBIC 2017b) although shortnose suckers enter the canal system within both sub-basins and are regularly salvaged by Reclamation once canals are drained after the irrigation season (Hodge and Buettner 2009). In the Lake Ewauna-Upper Klamath watershed, 19 intermittent streams would be crossed by dry open-cut and 6 others by boring. In the Mills Creek-Lost River watershed, 40 intermittent streams would be crossed by dry open-cut and 19 others by boring. There is no information documenting that shortnose suckers would be present in any of those intermittent streams, which include canals and ditches, at the time of construction (discussed above). The Lost River will be crossed using dry open-cut construction.

Direct and Indirect Effects

<u>Timing</u>

The Klamath River (MP 199.38) and the Lost River (MP 212.07) are the only perennial waterbodies crossed by the ipeline on Construction Spread 5. The ODFW (2008) allows instream construction in the Klamath River (above Keno) from July 1 to January 31 and in the Lost River (below Bonanza) from July 1 to March 31. PCGP has requested that HDD crossing the Klamath River be allowed to occur outside of ODFW's in-water construction windows to ensure that enough time is provided to successfully complete the crossings. PCGP proposes cross the Klamath River using HDD crossing methods between July and October. The Lost River would be crossed by dry-open crossing methods during the ODFW-recommended crossing window (July 1 to March 31). Spawning occurs within limited areas of the Lost River (Reclamation 2007), and occasional individual shortnose suckers have been found in this stream region, so it is possible that shortnose suckers be present in the Lost River where the Pipeline would cross during the non-spawning period.

<u>Species Presence</u>

In the vicinity of the Pipeline, shortnose suckers occur in the Lake Ewauna-Klamath River 5th field watershed and the Mills Creek-Lost River 5th field watershed. The pipeline route crosses the Lake Ewauna-Klamath River 5th field watershed for about 17.24 miles (MPs 188.41 to

205.65) and the Mills Creek-Lost River 5th field watershed for 23.15 miles (MPs 205.66 to 228.81). The Pipeline will cross 26 waterbodies in the Lake Ewauna-Klamath River, one by HDD, six by conventional bore, and 19 by dry open-cut, and will cross 59 waterbodies in the Mills Creek-Lost River watershed, 20 by conventional bore and 39 by dry open-cut.

Potential effects to shortnose suckers inhabiting Klamath River by HDD construction are discussed below. Since there will be no instream work for any of the conventional bore crossings, no effects to shortnose suckers are expected in those 26 streams, canals, drains or ditches that are maintained by the BOR. Potential effects to shortnose suckers are possible in waterbodies crossed by dry open-cut, including the Lost River (known to be occupied by shortnose suckers) with the exception of 26 waterbodies crossed between MP 214.38 and MP 228.81. At MP 214.38, the pipeline route deviates from the general west to east direction and proceeds north, up a 9 percent slope (climbing from 4,100 feet to 4,360 feet elevation) to MP 215.04, and then continues to the east along a ridgeline (paralleling powerline corridors) to MP 228.81. In that segment, the route crosses 26 waterbodies that are intermittent headwater drainages with unlikely (due to steep slopes) or no pathways (no connectivity) for shortnose suckers to enter from lowland BOR canals, drains or ditches that might support Lost River suckers and shortnose suckers. No effects to shortnose suckers would occur by crossing those 26 waterbodies.

Potential effects to shortnose suckers are possible during dry open-cuts of 19 waterbodies crossed in the Lake Ewauna-Klamath River watershed and the remaining 13 waterbodies west of MP 214.38 crossed in the Mills Creek-Lost River watershed included in table 3.5.5-2 (in Lost River sucker section 3.5.5). Except for the Lost River and one irrigation ditch at MP 194.64, none of the waterbodies have been mapped by the Klamath Project. Consequently, connectivity of those other 30 waterbodies (classified as ditches) to larger canals and laterals that may seasonally support shortnose suckers cannot be determined.

Suspended Sediment by Pipeline Crossing Methods

Potential occurrence of shortnose suckers in waterbodies crossed by dry open-cut are included in table 3.5.5-2. Dry crossing methods would result in minimal impacts, including temporary increases in suspended sediments in restricted areas. One HDD and 25 conventional bores would be installed without in-water work and would not directly affect the aquatic environment and associated species (except in the case of an inadvertent return during an HDD crossing, which could affect stream suspended sediment levels as discussed below). The Klamath River would be crossed with an HDD.

Since all streams/ditches crossed, except for the Klamath River and Lost River, are minor or intermediate channels, any construction required would be done in the dry, reducing potential for any adverse suspended sediment conditions downstream. Additionally, road crossings where fish may be present would be constructed to meet ODFW fish passage standards so fish movement would not be blocked. While some elevated sediment may occur downstream, effects would be unsubstantial to shortnose sucker due to the implementation of approved construction methods.

Suspended Sediment – Dry Open Cut

Pipeline crossings of surface waterbodies would cause some downstream turbidity and sedimentation. The type of crossing and stream sediment characteristics can affect turbidity and suspended sediment in streams. The dry crossing methods to be used are flumed or dam-and-pump:

- **Flume.** The flume method typically is used to cross small to intermediate flowing waterbodies that are either fish-bearing or non-fish-bearing streams. The flume technique involves diversion of stream flow into a carefully positioned steel pipe of suitable diameter to convey the maximum flow of the stream across the work area and ensures that stream flow rate is not interrupted.
- **Dam-and-Pump.** With the dam-and-pump method, stream flow is diverted around the work area by pumping water through hoses over or around the construction work area. The goal of this technique is to create a relatively "dry" work area to avoid or minimize the transportation of heavy sediment loads and turbidity downstream of the crossing. This crossing method may be used on all waterbodies where stream flow can be diverted by pumping around the work area.

As noted in section 3.5.3.3, Coho Salmon (SONCC ESU), dry open-cutting (fluming, dam-and-pump, or some combination of the two) generates small amounts of turbidity compared to wet open-cut procedures. However, adult suckers appear to prefer deep, turbid water but are often forced to utilize shallow, clear water during degraded water quality conditions in the summer (NRC 2004). The amounts of turbidity generated by dry open-cut construction may cause minor short-term adverse effects to shortnose suckers if they are within several hundred feet downstream of the Lost River crossing site. However, guidance for evaluating effects of exposure and dose of suspended sediments on catostomids (including shortnose sucker) is not available, similar to documentation for salmonids (e.g., Newcombe and Jensen 1996). Crossing of the intermittent channels is planned to occur in the dry so suspended sediment increases should be very low when flow is returned to the channels, as channel conditions would be stabilized. Should a crossing occur when flow is present, some suspended sediment levels would be more elevated. However, considering 1) the small size of these intermediate streams/ditches, 2) the short duration of construction activity at each crossing location, 3) the expectation that suckers would not be present in these streams/ditches, even when they are flowing, and 4) the apparent tolerance of this species for turbid water, these elevated suspended sediment levels would not cause substantial adverse effects to shortnose suckers in these intermittent flow crossings.

There is a possibility that following construction, future flows returning to the ditches listed in table 3.5.5-2 could potentially indirectly affect suckers by mobilizing sediment replaced over the trench. Mobilized sediments could lead to downstream sediment impacts on forage species, streambank erosion and stability (geotechnical stability), and surface flow retention. However, during delineation of the ditches, field personnel reported stream gradients at ditches as <1% and many had mud substrates, both observations indicative of low instream flows and velocities in the ditches. Consequently, flows returning in the ditches after dry open-cut construction may not be sufficient to mobilize native materials replaced in the trench. PCGP (in the ECRP/appendix F) has proposed to install erosion control matting to cover channel bottoms where revegetation of the channel bottom is required. Erosion control matting, anchored with staples to the channel sides and bottom, could be similarly used at irrigation ditches to minimize risk of sediment mobilization, downstream sediment impacts on forage species (zooplankton such as cladocerans – water fleas – and benthic insects such as chironomid midge larvae and amphipods), and streambank erosion and stability. Use of erosion control matting would allow materials replaced as bottom substrate and restored ditch banks to consolidate without eroding until the matting degrades.

Suspended Sediment – HDD

The HDD installation method is considered an effective technique for avoiding in-stream impacts by eliminating the need for in-stream excavation (Reid and Anderson 1998; Reid et al. 2004). According to GeoEngineers' (2017g) analysis for construction using HDD across the Klamath River (see appendix E), the design length of the Klamath River HDD crossing would be approximately 2,300 feet. The proposed Klamath River entry point would be in an agricultural field about 950 feet east of the river bank and the exit would be an open area about 370 feet west of the river bank. The HDD design indicates there would be between 70 and 140 feet of streambed cover in the river channel over the pipe. .There is no direct in-stream disturbance so no suspended sediment increases would occur unless there is an unplanned drilling failure. There would be a moderate to high risk of hydraulic fracture from the entry point to about 900 feet to the west, all within the east bank of the river. The portion of HDD beneath the river would be below bedrock with a low risk of a release of drilling mud ("inadvertent return"). The risk of inadvertent return would be high within 425 feet from the HDD exit point on the west bank of the Klamath River due to presence of stiff silt alluvium (GeoEngineers 2017g). Though the risk of releasing drilling mud directly beneath the riverbed is low, such a release could have impacts on the aquatic environment and species.

Inadvertent Release of Drilling Muds (Inadvertent Return). However, there is a potential for impact as a result of the HDD process. Drilling requires use of a drilling mud for lubrication of the bit and removal of cuttings. A non-toxic, biodegradable bentonite clay mixture makes up drilling mud. Because the drilling mud is under pressure during drilling, if the bit encounters substrate fractures or channels, it is possible for bentonite to escape from the drilled hole (termed an "inadvertent return"). Bentonite can escape to the surface through fractures in the drilled substrate. Bentonite by itself is a non-toxic drilling mud (Breteler et al. 1985; Hartman and Martin 1984; Sprague and Logan 1979) although according to Reid and Anderson (1998), the toxicity of bentonite (sodium montmorillonite) in fresh water ranges from 5,000 to 19,000 ppm (mg/liter) based on 96-hour tests for LC50 (the concentration at which 50 percent of the test population dies after 95 hours of exposure) on rainbow trout. The toxicity classifications based on LC50 values ranged from "slightly toxic" to "practically non-toxic" (Reid and Anderson, 1998). In other tests, toxicities to lake whitefish and rainbow trout demonstrated threshold concentrations of 16,613 and 49,838 ppm (mg/liter), respectively (Reid and Anderson, 1998). LC50 concentrations > 10,000 ppm would be considered "practically non-toxic" (Reid and Anderson 1998). As with any fine particulate material, bentonite can interfere with oxygen exchange by gills and the degree of interference generally increases with water temperature.

The summary by Reid and Anderson (1998) provides a substantive description of effects to streams and habitat in the cases with inadvertent returns.

Drilling mud releases during HDD construction can result from:

1. Circulation losses through highly permeable gravels;
2. Mud migration along rock joints or fractures which intersect with the river bottom;
3. Loss of pilot hole directional control resulting in the intersection with the river bottom or approach slope;
4. Drilling mud pressures exceeding ground stress, widening existing or creating new

fractures (hydraulic fracturing), allowing for mud migration;
5. Substantially different elevations of entry and exit drill locations. Resulting pressure head differences can cause substantial upland leakages of drilling muds once the drill bit nears the ground surface or when it breaks the surface.

Drilling mud releases may surface through river and streambeds, wetland bottoms, or at upland locations. The volume of mud released to the surface would depend on:

1. Porosity of the substrate transporting the mud;
2. Extent and size of the porous material;
3. Pressure exerted on the mud by the hydraulic system;
4. Viscosity of the mud at the time of exposure;
5. Whether mud circulation can be maintained.

Magnitude of effects by mud releases to fish, streams and habitat would depend on the following (page numbers referenced from Reid and Anderson, 1998):

1. Toxicity of the drilling mud components and additives (pages 57-59 and Table 1);
2. Increased sediment loads (page 59);
3. Effects to hydrological conditions that would cause poor conditions for wetland plant establishment and growth (pages 59-60);
4. Release into streams and rivers could cause increases in the downstream drift of stream macroinvertebrates (page 60);
5. Effects on fish would depend on level of exposure (e.g., concentration) and duration of exposure and lifestage of fish present, timing of release, and ability of the watercourse to remove or incorporate the released muds without degrading existing habitats (page 61).

The report by Reid and Anderson (1998) summarizes the general effects, known or hypothesized, associated with drilling mud releases but does not provide specific effects associated with each of the instances of inadvertent returns cited.

Likewise, Canadian Pipeline Water Crossing Committee (1999) reported that drill mud seepage occurred in 36 of 146 HDD cases reviewed with most significant leakage occurring at the drill entry or exit points due to different pressure heads with large differences in elevation between the two points. Leakage also occurred during reaming or pull-back. However, the report did not describe the effects to fish, streams, and habitat in the cases with leakages or inadvertent returns.

Potential inadvertent returns are more common near the HDD drill entry and exit locations; however, impacts to waterbodies are minimized by locating the drill entry and exit points away from the waterbody.

If an inadvertent return occurs into the river, drilling fluid would enter the waterway causing short-term, temporary water quality impacts downstream of the Pipeline project area including sedimentation and turbidity. Should this occur, fish would likely avoid the immediate vicinity of any elevated suspended sediment within this larger river crossing area.

If drilling fluid accumulates in the substrate, it can adversely impact the quality and quantity of aquatic habitat available for aquatic species including catostomid (sucker) spawning habitat and benthic macroinvertebrate rearing habitat. Drilling fluid that accumulates in the substrate may cover up food sources and smother fish eggs and other aquatic life in the riverbed. However, significant impacts to substrate from inadvertent returns are not likely in large river systems because of the anticipated high water volumes and velocities within large rivers. PCGP developed its *Drilling Fluid Contingency Plan for Horizontal Directional Drilling Operations* (see appendix D), which describes how the drilling operations would be conducted and monitored to minimize the potential for inadvertent drilling mud releases. The HDD Contingency Plan also includes procedures for cleanup of drilling mud releases. As discussed above for Lost River suckers, if drilling fluid is inadvertently released into the Klamath River and significant concentrations are found during monitoring as a result of a release, the following possible corrective measures would be taken:

1. Deployment of containment structures, if feasible, and removal of drilling mud from substrate and streambanks if possible.
2. Increase the drilling fluid viscosity in an attempt at sealing the point at which fluid is leaving the drilled hole. The drilling operation may be suspended for a short period (i.e., overnight) to allow the fractured zone to become sealed with the higher viscosity drilling fluid.
3. If increasing the drilling fluid viscosity is ineffective, lost circulation materials (LCM) may be introduced into the hole by incorporating them in the drilling fluid and pumping the material down-hole. The drilling operation may again be suspended for a short period (i.e., overnight) to allow the fractured zone to become sealed with the LCMs.
4. Depending on the location of the fractured zone, a steel casing may be installed that is of sufficient size to receive the largest expected down-hole tools for the crossing. This casing installation provides a temporary conduit for drilling fluids to flow while opening the remaining section of the hole to a diameter acceptable for receiving the proposed pipe sections. To alleviate future concerns with the steel casing after the HDD installation is completed, the casing is generally extracted from the hole prior to or just after completing the HDD installation. However, there have been instances when attempts at extracting the steel casing were unsuccessful.
5. In the event drilling fluid flow is not regained through the annulus of the drilled hole and a steel casing installation is not utilized, the HDD contractor may elect to install a grout mixture into the drilled hole in an attempt to seal the fractured zone. The down-hole drilling assembly is generally extracted and existing hole is re-drilled to the point at which it had previously been drilled prior to having encountered the loss of drilling fluid.

In some instances, it may be determined that the existing hole encountered a zone of unsatisfactory soil material and the hole may have to be abandoned. If the hole is abandoned, it would be filled with cuttings and drilling fluid.

Overall, at the site of any inadvertent return, the amount of drilling mud released into a waterbody would be low. The HDD location would be under the Klamath River with large volumes of water and swift flows where the drilling mud would be diluted. If an inadvertent release of drilling mud from an HDD occurred it would have minor short-term adverse effects to aquatic resources including shortnose sucker.

Movement Blockage

Dry open-cut construction is expected to block short-term movements of shortnose sucker, possibly in the Lost River, but likely not in other crossings as shortnose sucker would unlikely be present in these areas. Restrictions on movement would be at most short-term. The fluming process is expected to require about 36 to 96 hours of in-stream work while dam-and-pump construction is expected to require between 20 and 56 hours of in-stream work (Reid et al. 2004).

During this time, fish may be exposed to suspended sediment levels that they may avoid. Flumes would maintain streamflow and fish might move upstream or downstream through the flume, but fish would be unable to move past a dam-and-pump crossing until it was removed. Flumes and dams would be removed as soon as possible following backfilling of the trench. Normal migration of adult shortnose suckers to spawning areas would likely be in the mid-winter to spring as spawning occurs from late February to early June, so short-term blockages could affect spawning migration due to the in-stream work extending to the end of March. Overall, the levels of suspended sediment and physical structure blockages would not cause substantial delays to shortnose sucker movement, resulting in unsubstantial effects to shortnose sucker individuals.

Entrainment and Entrapment

Waterbody crossings using the "dry" crossing methods, flume or dam-and-pump, may result in some fish being entrapped in streams. Flumes and dams would be completely installed and functioning before any instream trenching disturbance occurs. Construction across a waterbody would take up to four days using dry open cut methods, but less for small and intermediate streams. Fish inadvertently left within the dammed-off construction zone could be killed by impingement on pump intakes used to dewater the construction zone or would likely die once all water was removed. Waterbodies crossed by dry open-cut (the Lost River and 31 ditches) with known or potential species presence are included in table 3.5.5-2.

For typical crossings once streamflow is diverted through the flume pipe, but before trenching begins, fish trapped in any water remaining in the work area between the dams would be removed and released (salvaged) using the *Fish Salvage Plan* (see Fish Salvage Plan under section 3.5.6.4 or appendix T for details). Salvage methods could include seines and/or dip nets and electrofishing. Seining would be the primary method used to salvage fish but electrofishing methods may be used if all fish cannot be removed from the area potentially dewatered. The *Fish Salvage Plan* incorporates these methods to minimize adverse effects to listed fish.

Suckers as a group (family Catostomidae) appear to be susceptible to many of the same deleterious effects from electroshocking that were described above for salmonids (Snyder 2004). Although records of the effects by electroshock to shortnose suckers have not been compiled, responses by river carpsucker, longnose sucker, white sucker, and razorback sucker among others indicate that they are particularly susceptible to spinal injuries and hemorrhages by electrofishing (Snyder 2004). Reclamation has salvaged fish from canals throughout the Klamath Project each fall since 1991 following dewatering using electofishing techniques (Reclamation 2008). Reclamation has noted that if electrofishing is found to injure juvenile suckers, they would pursue other techniques to salvage fish (Reclamation 2008). Sucker mortalities (Lost River suckers, shortnose suckers, and Klamath largescale suckers) have occurred during salvage operations, whether due to electrofishing stress or to low levels of DO (Peck 2000 and 2001). Reclamation has also done annual fish salvages in the forebay of a fish screen facility using backpack electrofishers and beach seines. This annual salvage procedure alleviates potential mass mortality of all fish at the fish screen as water is removed (Reclamation 2007).

All methods of capture and holding have risks of stress, injury, or mortality of fish. In conjunction to implementation of the *Fish Salvage Plan*, PCGP would contract with either ODFW or a qualified consultant to capture the fish. Fish removal personnel will be approved by ODFW and NMFS for this listed species. Personnel who would handle and/or remove fish on federal lands would also be approved by the Forest Service or the BLM, or the work would be done directly by agency personnel if approved by ODFW. Overall, some listed juvenile shortnose sucker may suffer injury or mortality, but with the implementation of conservation measures the numbers would be slight.

Acoustic Shock and Underwater Noise

There would be no blasting or use of mounted hydraulic impact hammer to cross the Lost River where shortnose suckers may be present or any of the 31 ditches with potential species presence included in table 3.5.5-2. Use of back-hoes for dry open-cut construction would not produce sound levels to cause harm to shortnose suckers, as discussed for SONCC coho salmon in section 3.5.3.3.

Riparian Vegetation Removal, Modification, and LWD Loss

Aquatic resources, including shortnose suckers and their habitat components, could be affected as a result of removal of vegetation and instream habitat at the waterbody crossing sites as required for construction. Short-term physical habitat disruption would occur during trenching activities. Long-term degradation of habitats could occur if the stream contours are modified in the area of the crossing, the flow patterns are changed, or erosion of the bed, banks, or adjacent upland areas introduces sediment into the waterbody. Loss of riparian vegetation along the banks would remove an important source of terrestrial food for aquatic organisms; and potentially increase mass slope failures adjacent to waterbodies.

Because HDD would be used to cross the Klamath River, only 0.04 acre (Urban or Built-up land) within the Klamath River riparian zone (extending 117 feet or one site-potential tree height from each river bank) would be affected. No forested riparian vegetation would be affected. Construction across the Lost River would disturb approximately 1.35 acres of agricultural land within the riparian zone (extending 119 feet from each river bank). Similar to the Klamath River crossing, no forested riparian vegetation would be affected or removed and all effects would be to agricultural land. Riparian zones associated with the Klamath River and Lost River crossings are on land owned by the State of Oregon. Riparian Zones for all other waterbodies crossed that are within range of the shortnose sucker are on private lands. All crossings other than the Klamath River and Lost River are on intermittent streams/ditches/canals with very limited low-growing riparian vegetation and would have unsubstantial reduction in near-stream vegetation from crossing clearing. Likewise, as there are few trees in the riparian area along the route in the range of the shortnose sucker, there would be no change in LWD supply to any stream system from construction of right-of-way clearing or maintenance.

Overall, there would be no substantial change in riparian vegetation or LWD supply along the route where shortnose sucker may be present. As a result, ecological function (e.g., supply of shade, future LWD, and organic input) of the riparian conditions would be maintained and adverse effects to the shortnose sucker would not occur from right-of-way clearing at stream crossings.

Water Temperature

Shortnose suckers are susceptible to water temperatures 85°F or higher (Bellerud and Saiki 1995) but prefer water temperatures between 60 and 77°F (FWS 2007f). As discussed above, no riparian vegetation would be removed that otherwise would provide shade. Consequently, water temperature would not be affected by construction in the Lost River and Klamath River.

Aquatic Habitat

There also are potential indirect effects to aquatic habitat from increased suspended sediment from stream crossings. As discussed for SONCC coho salmon, suspended sediment released during stream crossing construction may have downstream habitat effects as well as direct fish effects such as changing substrate conditions (e.g., elevated fines) that may affect benthic food resources. Only one stream, the Lost River, is known to be crossed with stream bottom substrate-disturbing activities during flowing periods; 31 ditches with potential for species included in table 3.5.5-2 are expected to be crossed in the dry and could have suckers present in the crossing area. Estimates of sediment generated by dry open-cut construction along other portions of the Pipeline route and implementation of BMPs would not result in short-term sediment elevations that could have substantial downstream adverse habitat effects that would indirectly affect the shortnose sucker or the species habitat.

Freshwater Stream Invertebrates

Substrates downstream from in-stream construction sites could be impacted by sediments which could affect forage species used by shortnose suckers. Mayflies, caddisflies, and stoneflies prefer large substrate particles in riffles and are adversely affected by fine sediment deposited in interparticulate spaces (Cordone and Kelley 1961; Waters 1995; Harrison et al. 2007). Suckers feed on benthic organisms including algae and invertebrates so reductions could affect their growth and survival. Fish and benthic macroinvertebrate abundance downstream of pipeline construction sites have been reported as short-term reductions (Reid and Anderson 1999). Macroinvertebrate abundance and community composition are highly related to the degree to which substrate particles are embedded by fine material (Birtwell 1999). Data below wet open-cut crossings, which generate much higher sediment levels than dry-cut crossings, generally found negative changes in benthic invertebrate populations were not apparent within a year (Reid et al. 2008) and some data found rapid recolonization of substrate within 30 days (Gartman 1984). Therefore, the overall level of effect of the pipeline crossings on waterbodies crossed by dry open-cut (the Lost River and 31 ditches) with known or potential species presence included in table 3.5.5-2 (unless crossing sealing failures at isolation structures occur), would be even less than those noted by literature and would not result in substantial reduction in growth or survival of listed shortnose sucker individuals.

Streambank Erosion and Streambed Stability

Clearing and grading activities during construction could increase erosion along streambanks resulting in higher turbidity levels in the waterbodies crossed. Alteration of the natural drainage ways or compaction of soils by heavy equipment near streambanks during construction may accelerate erosion of the banks, runoff, and the transportation of sediments into waterbodies. Erosion, sedimentation, and higher turbidity levels related to the Pipeline project could affect aquatic resources in waterbodies crossed by dry open-cut (the Lost River and 31 ditches) with known or potential species presence (included in table 3.5.5-2). The degree of impact on aquatic organisms due to erosion would depend on sediment loads, stream velocity, turbulence, streambank composition, and sediment particle size.

Alteration of the natural drainage ways or compaction of soils by heavy equipment near streambanks during construction may accelerate erosion of the banks, runoff, and the transportation of sediments into waterbodies. The degree of impact on aquatic organisms due to erosion would depend on sediment loads, stream velocity, turbulence, streambank composition, and sediment particle size. To minimize these impacts, PCGP would use temporary equipment bridges, mats, and pads to support equipment that must cross the waterbody (perennial, intermittent, and ephemeral if water is present) or work in saturated soils adjacent to the waterbody. PCGP would also install sediment barriers, such as silt fence and straw/hay bales, across the right-of-way at the edge of waterbodies throughout construction except for short periods when the removal of these sediment barriers is necessary to dig the trench, install the pipe, and restore the right-of way. Practices to minimize streambank erosion are provided in the ECRP (see appendix F).

The FWS expressed concerns that more detailed site-specific information on bank material, streambed composition, shoreline vegetation, and other information is needed to adequately ensure that actions occurring at a stream crossing do not significantly increase streambank erosion and streambed instability. PCGP, in response to these requests, conducted an assessment of crossing conditions of all streams suitable for analysis based on the FWS risk matrix (GeoEngineers 2017d and 2017e). As discussed for SONCC coho salmon, PCGP used this matrix to rate crossings for risk of potential stream bank and channel changes. Based on the GeoEngineers (2017d and 2017e) Risk Matrix analysis, the Lost River crossing has a "high" level of risk based on existing stream site sensitivity based on the landscape/stream type (channel characteristics), riparian conditions (essentially none), and bed conditions (sand). If any crossing is moved into the "high" impact and "high" stream response risk matrix category, a site-specific crossing design would be developed for that site. Construction would then move forward as described in the permit documents including implementation of special additional BMPs, as described in GeoEngineers (2017d and 2017e), depending on individual site conditions and may include such actions as changes in bank material and bank angle modifications, specific substrate composition used, plants used on the bank, artificial stabilizing bank material, rootwad enhancement, and various other actions. These actions would reduce potential adverse effects from bank and bed stability to unsubstantial levels to the listed shortnose sucker.

Hydrostatic Testing

Water would be required on a one-time basis near the end of construction to hydrostatically test the pipeline. Potential impacts associated with hydrostatic testing include entrainment of fish; transfer of exotic organisms between basins; reduced downstream flows and impaired downstream uses if test water is withdrawn from surface waters; and erosion, scouring, and release of chemical additives as a result of test water discharge. PCGP would obtain its hydrostatic test water from commercial or municipal sources or surface water rights owners, the sources of which are lakes, impoundments, and streams.

Within the range of the shortnose sucker, there are four potential water sources, including John C. Boyle Reservoir, Keno Reservoir, Klamath River, and High Line Canal. There are 5 potential discharge locations, all of which are within the right-of-way. None of the hydrostatic test break sections are in the vicinity of a waterbody with known shortnose sucker occupancy or critical habitat. Discharge volume at each site ranges from 0.63 to 4.6 million gallons. The largest withdrawal is proposed from the Klamath River or High Line Canal. Water withdrawn from Keno Reservoir at Keno Dam would be from designated critical habitat for shortnose suckers. Water will also be withdrawn from John C. Boyle Reservoir at the Spencer Bridge. Although the reservoir is not included in designated critical habitat, shortnose suckers are expected to be present. As with Lost River suckers, water withdrawals from occupied habitats risk entrainment and impingement. The screening of intake hoses would be used to prevent the entrainment of fish and other aquatic organisms, meeting NMFS screening criteria. The rate of withdrawal would also be regulated to avoid adverse impact on aquatic resources or downstream flows (NMFS 1997c).

PCGP would minimize the potential effects of hydrostatic testing by adhering to the measures in its *Hydrostatic Testing Plan* (see appendix U). Where test water cannot be returned to its withdrawal source, the water would be treated and discharged to an upland location (at least 150 feet from wetlands or waterbodies with no direct discharge to these features) through a dewatering device at a rate to prevent scour and erosion and to promote infiltration. PCGP would obtain all necessary appropriations, withdrawal, and discharge permits through the OWRD.

With the implementation of the *Hydrostatic Testing Plan* and BMPs and by obtaining required permits, adequate measures would be in place to prevent direct or indirect effects of hydrostatic testing to shortnose sucker that may be in some of the stream systems.

Aquatic Nuisance Species

NAS are aquatic species that degrade aquatic ecosystem function and benefits, in some cases completely altering aquatic systems by displacing native species, degrading water quality, altering trophic dynamics, and restricting beneficial uses (Hanson and Sytsma 2001). Currently, there are 180 reported NAS in Oregon, of which 134 are documented within the USGS hydrologic basins crossed by the Pipeline (USGS 2017).

In the riverine environments crossed by the Pipeline, largemouth and smallmouth bass, introduced as recreational species, prey on juvenile sockeye, coho, and Chinook salmon (Tabor et al. 2007). Additionally, up to 20 exotic species (many of which can reside in streams including largemouth bass, yellow perch, and fathead minnow) are present in the range of shortnose sucker and are suspected to compete and prey on them (FWS 2013). Management priorities in Oregon concentrate on aquatic nuisance species, which are the species whose current or potential impacts on native species and habitats and economic and recreational activity in Oregon are known to be significant (Hanson and Sytsma 2001). Some of the major potential freshwater invasive species are Chytrid fungus and mussels, including the zebra and quagga mussels (*Dreissena polymorpha*, and *Dreissena rostriformis bugenisis*).

Aquatic nuisance species could potentially be introduced into Pipeline project area waters by interbasin transfer of hydrostatic testing water or by being carried on equipment that is moved from outside of the region or between basins. PCGP has developed BMPs and guidelines to avoid the potential spread of aquatic invasive species (see *Hydrostatic Testing Plan* in appendix U*)* in consultation with the BLM and Forest Service as well as with ODEQ and the Center for Lakes and Reservoirs and Aquatic Bioinvasion Research and Policy Institute (Portland State University).

If determined to be feasible, all water used in hydrostatic testing would be returned to its withdrawal source location after use; however, cascading water from one test section to another to minimize water withdrawal requirements may make it impractical to release water within the same watershed where the water was withdrawn. If it is not possible to return the water to the same basin from which it was withdrawn, PCGP would employ an effective and practical water treatment method (chlorination, screening/filtration, or other appropriate method) to disinfect the water that would be transferred across basin boundaries. The hydrostatic test water would be treated after it is withdrawn and prior to hydrostatic testing.

PCGP would implement a three-step BMP treatment process to prevent the potential spread of invasive species and forest pathogens from non-municipal surface water sources used during hydrostatic testing. The hydrostatic test water treatment process would incorporate screening/filtration during water withdrawal, chlorine treatment, and upland discharge at least 150 feet from wetlands or waterbodies with no direct discharge to these features. All hydrostatic test water will be released through a dewatering device such as a straw bale structure or sediment bag in a manner to promote infiltration. Further, all hydrostatic release locations would be monitored after construction to ensure noxious weeds have not established.

As explained in the *Hydrostatic Testing Plan*, PCGP proposes to use a treatment of 2 ppm or 2 mg/L of free chlorine residual with a detention time of 30 minutes to treat all non-municipal surface waters that would be used as a water source for hydrostatic testing purposes. Chlorinated water would be released according to the Oregon Department of Environmental Quality criteria to prevent water quality impacts, potential effects to aquatic species, and minimize potential impacts to sensitive areas.

The potential for dispersal of aquatic nuisance organisms by other construction equipment and vehicles from one basin to another is remote. The BMPs in the noxious weed control procedures outlined in the ECRP (see appendix F) and the Integrated Pest Management Plan (see appendix N to the POD) would be employed to prevent the introduction and spread of invasive species from construction. With the implementation of these noxious weed control measures, introduction of nonnative species or movement of species between basins should not occur, resulting in no adverse effects to the listed shortnose sucker.

Fuel and Chemical Spills

Fisheries habitats could be adversely affected if petroleum products were accidentally discharged into aquatic environments including waterbodies crossed by dry open-cut (the Lost River and 31 ditches) with known or potential species presence that are included in table 3.5.5-2. Such materials are toxic to algae, invertebrates, and fish. Of the products likely to be present during construction, data compiled from a wide range of sources indicate that diesel fuels and lubricating oils are considerably more toxic to aquatic organisms than other, more volatile products (gasoline) or heavier crude oil (Markarian et al. 1994). For example, one study reported that release of diesel fuel in freshwater habitats significantly reduced aquatic invertebrate densities and species richness at least three miles downstream but invertebrate densities recovered within a year (Lytle and Peckarsky 2001). Impacts to aquatic habitats that primarily affect aquatic substrates—hence spawning, incubating, and rearing habitats—can remain for much longer periods (Markarian et al. 1994).

Equipment used for construction across waterbodies could potentially release hydraulic fluid comprised of a variety of compounds, the most common of which are mineral oil-based, organophosphate esters, and polyalphaolefins (HHS 1997). Release from machinery can occur through faulty seals, hoses, sumps and reservoirs, or general system failure.

Inadvertent spills of fluids used during construction, such as fuels and lubricants, could contaminate wetland soils and vegetation if not sufficiently contained. To minimize the potential for spills and any impacts from such spills, PCGP's SPCCP (see appendix L) would be implemented. In general, hazardous materials, chemicals, fuels, lubricating oils, and concrete-coating activities would not be stored, nor would refueling operations be conducted, within 100 feet (150 feet on BLM and NFS lands) of a wetland or waterbody in accordance with FERC's

Procedures (see appendix C) and the SPCCP (see appendix L) except where no reasonable location is possible and additional containment steps have been taken. The SPCCP would be updated with site-specific information prior to construction. Adherence to these plans and procedures would result in effects to the listed shortnose sucker that would be unsubstantial.

Runoff from Facility Surfaces

There are nine contractor and pipe storage yards, one rock source and disposal site, two new temporary access roads, two new permanent access roads, and three aboveground facilities including the Klamath Compressor Station within the range of shortnose suckers.

Two of the yards, K-Falls Memorial Dr 1 Yard and K-Falls Memorial Dr 2 / Bair Yard, border the Klamath River, and the K-Falls - Industrial Oil Yard is about 235 feet from the Klamath River which is designated critical habitat for shortnose suckers. The Klamath Compressor Station is about 700 feet from the T Canal, for which there are no records of shortnose sucker being present (construction and operation of the compressor station would not affect suckers even if present).

Stored materials at the yards may include: construction mats, fencing materials, fuel and lubricants, stormwater control materials (straw bales, erosion control fabric, silt fence materials, etc.), and other construction materials. The yards would also be used for contractor office trailers and employee parking facilities. Although the yards are previously disturbed industrial sites, there is some unknown level of risk that stored materials and surface runoff could enter shortnose sucker critical habitat. Runoff from any of these sites would be mitigated through measures provided in PCGP's ECRP (see appendix F).

Operation and Maintenance Activities

Once installed, maintenance of the pipeline would include activities such as aerial inspections, gas flow monitoring, visual inspection of surrounding vegetation for signs of leaks, and integrity management, which includes smart pigging to investigate the interior surface of the pipe for any signs of stress cracking, pitting, and other anomalies (see the ECRP, appendix F). All of the proposed maintenance activities would be outlined in the Operations and Maintenance Plan that would be prepared according to operating regulations in DOT 49 CFR Subpart L, Part 192 and would be completed prior to the Pipeline going in-service. These general maintenance activities would require only surface activities and usage of the existing right-of-way, such as insertion of the pig at one of the pig launching facilities.

The potential stream channel disturbance would occur if an integrity issue with the pipeline were found at a crossing location. If this were to occur, the pipeline would need to be unearthed within the right-of-way and repair work done in-water. Within stream sites, repair work could require isolated flow from the section of pipe that is to be exposed. Typically, repairs would be made to the pipe within the right-of-way (within the trench) or, depending on the site-specific conditions and nature of the repair needed, a reroute around the affected section may be considered.

Impacts would be similar to those discussed above for initial installation except on a much smaller scale because they would only involve one crossing compared to many crossings. However, should repairs be needed out of the standard stream crossing window (i.e., during periods of fish spawning or egg incubation) there would be additional adverse effects to key fish resources at the specific site. The actions would include all relevant BMPs and mitigation, dependent upon site conditions and land ownership. Any future repairs would require additional permit approval from appropriate state and federal agencies which would determine the acceptable parameters of these actions. Such pipeline integrity-based in-water projects are very infrequent.

Vegetation maintenance would be limited adjacent to waterbodies to allow a riparian strip to permanently revegetate with native plant species across the entire right-of-way. To facilitate periodic pipeline corrosion/leak surveys, a corridor centered on the pipeline and up to 10 feet wide would be maintained in an herbaceous state, with scrubs outside of this 10 foot corridor. In addition, trees that are located within 15 feet of the pipeline may be cut and removed from the right-of-way. No vegetation or tree limitations would occur beyond the 30 foot wide corridor in riparian areas (i.e., up to 100 feet of streams on federal lands and up to 25 feet of streams on non-federal lands). Since most native riparian vegetation along the Pipeline route has been altered by agriculture, the effects of maintaining the 30-foot wide corridor on Lost River sucker instream habitat would be minimal.

Herbicide Application

Herbicides have the potential to cause toxic effects to different sucker life stages and to other aquatic species, causing direct impacts, if used improperly. When herbicides are properly used according to label restrictions and BMPs to control noxious weeds, there is little to no chance of causing injury or mortality to fish or other aquatic organisms.

PCGP would not use herbicides for routine vegetation maintenance. However, following construction, PCGP would implement an Integrated Pest Management Plan (IPM - appendix N to PCGP's POD) that addresses control of noxious weeds and invasive plants across the Pipeline project which would include the selective use of herbicides where necessary to control noxious weeds by limited application from the ground, where allowed by landowners. The Integrated Pest Management Plan was developed in consultation with the ODA, BLM, and Forest Service. The BMPs would minimize the potential spread of invasive species and minimize the potential adverse effects of control treatments. Herbicides would not be applied by aerial or broadcast spraying. Noxious weeds would be removed only by manual methods in the riparian zone adjacent to streams, ditches and canals within the range of shortnose suckers. PCGP would not directly spray, or otherwise apply, herbicides in waterbodies or in riparian zones. The risk of drift would be avoided by selectively applying herbicides from the ground.

Where weed control is necessary along the construction right-of-way, PCGP's first priority would be to employ hand and mechanical methods (pulling, mowing, biological, disking, etc.) applicable to the species to prevent the spread of potential weed infestations, where feasible. To determine if an herbicide is to be used over other control methods, PCGP would base the decision on weed characteristics and integrated weed management principles (Forest Service 2005). If herbicides are used to control noxious weed infestations, they would be used when they are the most appropriate treatment method. Spot treatments and the use of selective herbicides would be utilized to minimize impact to native or non-target species. Permits or approvals for the use of herbicides and adjuvants on federal lands would be obtained prior to use/treatment, as detailed in the IPM (see appendix N to the POD, available upon request). Considering the potential for limited use of herbicides along the route and precautions that would be in place to prevent entry into waters, meaningful negative effects to the shortnose sucker from herbicides would be unlikely to occur.

Cumulative Effects

Within the action area, 100 percent of all lands are non-federal within the John C. Boyle Reservoir-Klamath River watershed, 99 percent are non-federal lands within the Lake Ewauna-Klamath River watershed, and 94 percent are non-federal lands within the Mills Creek-Lost River watershed. Degradation of water quality due to livestock grazing, agriculture, and timber harvest has resulted in severe pollution in Upper Klamath Lake. That in turn has led to algal blooms with increased mortality of suckers when oxygen depletions occur due to eutrophication particularly during summers when high temperatures combine with nutrient loading from pumping diked wetlands and runoff from farms. Past actions that have led to increased mortality have been due to private enterprise on private lands. Cumulative impacts on shortnose suckers would include those same or similar actions which are reasonably foreseeable during the next four years. Cumulative impact from non-federal actions on non-federal lands are ongoing and will continue into the future. The effect from the construction and operation of the Project is anticipated to be temporary and localized and would not measurably contribute to the current or future cumulative effects upon this species.

Critical Habitat

Designated critical habitat for the shortnose sucker is present within the Pipeline project area. The Pipeline would cross the Klamath River at RM 249, which is within critical habitat Unit 1, Klamath County (FWS 2012g). Unit 1 includes Upper Klamath Lake and Agency Lake, together with some wetland habitat; portions of the Williamson and Sprague Rivers; Link River; Lake Ewauna; and the Klamath River from the outlet of Lake Ewauna downstream to Keno Dam. Some or all of the three PCEs noted above (water, spawning and rearing habitat, and food) could be affected during the HDD across the Klamath River if a inadvertent return occurred with release of drilling mud into the water column; the same effects to critical habitat that were described as Direct and Indirect Effects, above, would occur.

Only 0.04 acre within the Klamath River riparian zone (extending 117 feet or one site-potential tree height from each river bank) would be affected by construction, and all of that area is in an existing industrial facility.

3.5.6.4 Conservation Measures

Conservation measures have been proposed by PCGP to minimize construction and operation impact to waterbodies and riparian zones within the riverine analysis area. Those measures have been compiled in table 2C in appendix N and apply to shortnose suckers.

PCGP has also proposed measures to rectify, repair, and rehabilitate and otherwise reduce impact to waterbodies and riparian zones once construction of the Pipeline is complete. Those measures have been compiled in table 3C in appendix N.

Details of some of the major conservation measures to be implemented by PCGP are summarized below.

Erosion Control

Many of the conservation measures in table 3C in appendix N focus on erosion control to prevent sediment from entering surface waters. Temporary erosion controls would be installed immediately after vegetation clearing and grading and would be properly maintained throughout construction and reinstalled as necessary until replaced by permanent erosion controls or restoration is complete. At a minimum, the following temporary erosion control structures would be installed: temporary slope breakers, sediment barriers, mulch, and erosion control fabric. PCGP would install permanent slope breakers consistent with the requirements of FERC's *Plan*. Part of long-term erosion control would include a final cleanup including final grading and installation of permanent erosion control structures. Final cleanup of an area would generally occur within 10 days after backfilling the trench and not be delayed beyond the end of the next recommended seeding season. During final cleanup, PCGP would remove all construction debris and grade disturbed areas to preconstruction grades to the extent practicable. An adequate seedbed would be prepared at the conclusion of cleanup.

Temporary Slope Breakers

PCGP would install temporary slope breakers over the backfilled, recontoured construction right-of-way as specified in FERC's *Plan*. The outfall of each temporary slope breaker would be to a stable, well-vegetated area or to an energy-dissipating device at the end of the slope breaker off the construction right-of-way. Slope breakers reduce runoff velocity, thereby intercepting sediment and allowing it to drop out of suspension. They also can effectively divert runoff away from a disturbed site to a stable outlet (Goldman et al. 1986).

Sediment Barriers

PCGP would primarily rely upon silt fence and staked hay or straw bales to confine sediment to the construction right-of-way. These structures would be used adjacent to wetland and waterbody crossings consistent with the requirements of FERC's *Procedures*. Straw bales and filter fabric (silt fence) can be used together to create a highly effective sediment barrier, a combination that compensates for the limitations of each used in isolation; straw bales provide extra support and the fabric provides greater filtering capability (Goldman et al. 1986).

All straw or hay bales used for sediment barriers would be certified as weed-free. Temporary sediment barriers would be maintained in-place until permanent revegetation measures are successful or until the upland areas adjacent to wetlands, waterbodies or roads are stabilized. The structures would be removed once vegetation in the area has been successfully restored.

Erosion Control Fabric

PCGP would install erosion control fabric (such as jute or excelsior) on waterbody banks at the time of recontouring. The fabric would be anchored using staples or other appropriate devices. Although there are no measures specific to pipeline construction, data related to cut-and-fill slopes treated during construction of forest roads indicate varying effectiveness of different types of stabilization measures designed to control surface erosion (EPA 2001). On fill slopes, combining straw mulch and netting decreased erosion by 99 percent. Excelsior mulch alone decreased erosion by 92 percent on fill slopes. On cut slopes, straw mulch by itself decreased erosion in a range from 32 to 97 percent (EPA 2001). Applications of mulches and/or fabric are effective measures promoting slope stabilization until vegetation can successfully be reestablished. These measures also promote plant growth (EPA 2001).

Fish Salvage Plan

Shortnose suckers can potentially occur within the construction right-of-way on the Lost River at the time of construction. Since the Lost River would be crossed using dry open-cut technology, fish salvage procedures (see section 3.5.3.4 for coho salmon SONCC ESU) may occur while fish, including shortnose suckers, are within isolated construction sites. Since suckers in general appear to be vulnerable to electroshocking, PCGP's fish salvage plan in the Lost River may have to avoid use of electroshock, relying instead on seining and dip-netting as described in section 3.5.3.4.

A *Fish Salvage Plan* has been provided in appendix T. The plan has been developed to minimize adverse effects to listed salmonids (SONCC coho, Oregon Coast coho), non-listed salmonids (Chinook salmon, steelhead, and cutthroat trout), and listed catostomids (Lost River sucker, shortnose sucker). The portions of the plan relevant to salvaging salmonids were adapted from the protocol developed by WSDOT (2011b). The protocol specifies procedures to 1) isolate the work area; 2) remove fish and dewater the work area; 3) handle, hold, and release fish; 4) document fish that have been captured, handled, held, and released; and 5) notify NMFS and FWS. The same protocol would generally be followed during salvage of Klamath Basin suckers. However, salvage operations within the crossing where these suckers may be present would include the latest *Handling Guidelines for Klamath Basin Suckers* (Reclamation 2008). These guidelines may be updated frequently. Some of the main factors in handling are the requirement of having a 0.5 percent saline solution of unchlorinated well water to place any captured listed sucker in should it be collected during fish salvage operations. Aeration would also be supplied and the container a sucker is placed into would have been coated with a commercially available slime coat. Fish would be retained in this solution until released upstream of the capture site unless otherwise indicated through agreement with FWS.

OHV Barriers

Limiting OHV access would reduce potential increased sedimentation to streams and human access to sensitive fish areas. In accordance with FERC's *Plan*, the applicant must offer to install and maintain measures to control unauthorized vehicle access to the right-of-way to each landowner or manager of forested lands. Such measures may include signs; fences with locking gates; slash and timber barriers, pipe barriers, or a line of boulders across the right of way; and conifers or other appropriate trees or shrubs across the right-of-way. If allowed by the landowner, and if available, slash, stumps, and/or logs would be placed on the right-of-way within the riparian zones to discourage OHV crossings of streams and to provide carbon and nutrients. If not allowed, PCGP would discuss with the landowner the use of other methods, as noted above. At a minimum, the area would be revegetated and re-seeded.

Streambank Stability

The root network of trees adjacent to streambanks is essential to maintaining streambank stability (WDNR 1997). Because root strength decreases significantly at distances beyond one-half the tree crown diameter, trees promoting streambank stability lie within half a tree crown diameter from the streambank. Trees within 25 feet of the streambank are assumed to promote streambank stability (WDNR 1997). Generally, trees that must be removed during construction would be cut at ground level with the roots left in place, except where located within the trenchline. Although roots would decay over time, streambank stability would be retained by their presence until revegetation is successful.

Streambank Restoration

PCGP's ECRP (see appendix F) describes the measures that would be used to stabilize streambanks crossed by the Pipeline. PCGP would not use riprap to stabilize streambanks. The alignment has been designed at waterbody crossings to be as perpendicular to the axis of the waterbody channel as engineering and routing constraints allow, minimizing streambank disturbance and avoiding parallel stream alignments or multiple stream crossings. Immediately after installation of a waterbody crossing, the contours of the streambed, shoreline, and streambanks would be restored to preconstruction configurations (i.e., contour/elevations) to restore the physical integrity/condition of these features and to minimize the loss of stream complexity.

PCGP has completed a scour analysis that would be used to ensure that appropriate pipeline burial depths and cover design parameters beneath channel streambeds and within adjacent floodplains are utilized, so that the effects on natural stream processes would be avoided or minimized. The Pipeline project's scour analysis, which was completed by GeoEngineers, was included in PCGP's September 2017 FERC certificate application.

PCGP would install erosion control fabric (such as jute or excelsior) on streambanks at the time of recontouring. The fabric would be anchored using staples or other appropriate devices. The erosion control fabric to be used on streambanks would be designed for the proposed use and would be approved by PCGP's environmental inspectors (EIs).

Consistent with the FERC's *Procedures* (section V.C.3.), during streambank restoration/recontouring, the streambanks would be returned to their preconstruction contours or to a stable configuration. The Lost River is included in the application of the conservation measure. Streambank revegetation measures, including supplemental riparian planting procedures, are also outlined in the ECRP. The shrubs and trees planted at each site would be determined at the time of planting based on the moisture regimes and site-specific conditions at each planting location and landowner requirements.

In-stream Gravel

Pipeline trenches across the Lost River and other perennial waterbodies within the Upper Klamath River Subbasin and Lost River Subbasin would be backfilled with material removed from the trench with the upper 1-foot of the trench backfilled with clean gravel or native cobbles of a size appropriate for resident fish, including suckers. The bottom and banks would be returned to preconstruction contours; banks would be stabilized; and temporary sediment barriers would be installed before returning flow to the waterbody channel.

Stream Crossing Risk Matrix

The FWS expressed concerns that more detailed site-specific information on bank material, streambed composition, shoreline vegetation, and other information is needed to adequately ensure that actions occurring at a stream crossing do not significantly increase streambank erosion and streambed instability. Follow-up surveys, site designs, and additional site actions resulting from these surveys as described below would reduce the risk of stream bank and bed instability in shortnose sucker habitat to unsubstantial adverse effects levels.

PCGP, in response to these requests, has conducted an assessment of crossing conditions of all streams suitable for analysis based on the FWS risk matrix (GeoEngineers 2017d, 2017e, and 2018a). GeoEngineers, using a combination of field and GIS data, rated proposed stream crossings based on the matrix along the entire route including 19 stream, ditch, and canal crossings in the range of shortnose sucker. The matrix has two axes rating the crossing based on the project impact potential at the crossing and the relative stream response potential at the crossing. Each crossing was rated as low, medium, or high for each of the two axes (all stream crossings were placed into one of nine categories, such as Low–Low, Low–Medium, and Medium–High).

No crossing within the range of the shortnose sucker was rated as having both high risk of project impact potential (i.e., high risk of project impacts and high risk of site response potential) and high risk of stream and site response potential. For any crossing in this category, PCGP would develop a site-specific crossing plan, similar to that required by FERC for stream crossings over 100 feet wide. All crossings that would have an open cut within the range of the shortnose sucker had moderate or low ratings for the two categories. The Lost River crossing was rated moderate project impact potential and high for the relative stream response potential.

Those stream crossings that were rated to have a low or moderate project impact potential would be crossed using project-typical BMPs. The remaining stream crossings would have a variety of site-specific BMP actions taken to reduce the probability of stream bank and bed erosion or instability from project actions (see pre-construction surveys below). Stream crossings that are unstable can ultimately adversely affect aquatic resources from such factors as loss of local habitat, impacts to downstream habitat from addition of high unstable sediment, and increased recovery time of the specific site to stable conditions.

A pre-construction survey would be conducted by a technically qualified team on all stream crossings to confirm and clarify conditions developed in the aforementioned matrix analysis. This team would be composed of professionals qualified to assess terrestrial and aquatic habitat and the geotechnical and geomorphic conditions relative to construction across stream channels and ditches. Following these surveys, if significant changes were to occur to parameters of the risk matrix for a crossing, changes would be made to risk level and appropriate final methods of crossing and BMPs made at each stream crossing. If any crossing is moved into the "high" project impact and "high" stream response risk matrix category, a site-specific crossing design would be developed for that site. Construction would then move forward as described in permit documents including implementation of special additional BMPs, as described in GeoEngineers (2017d, 2017e, and 2018a), depending on individual site conditions. Special additional BMPs may be such actions as changes in bank material and bank angle, specific substrate composition used, plants used on the bank, artificial stabilizing bank material, rootwad enhancement, and various other actions.

As a follow-up measure to help ensure crossing actions would not adversely affect stream bank and channel structure, PCGP would monitor stream crossings to ensure long-term success of the restoration, maintenance of fish passage, and to identify channel erosion, scour or migration that could destabilize the site or expose the pipeline. As requested by FERC, PCGP developed a monitoring plan (GeoEngineers 2017e and 2018a) following consultation with a representative from FWS and NMFS (Castro 2015). The monitoring plan would be customized, where necessary, to address risks of stream crossings identified in the Risk Analysis and those identified in subsequent preconstruction surveys.

Monitoring would consist of:

- Annual visits to all stream crossings, regardless of risk level, as part of PCGP's monitoring of pipeline integrity. These visits would be completed by PCGP staff and would note any obvious signs of channel erosion, pipeline exposure, or major shifts in restoration elements. Potential problem areas would be subsequently visited by PCGP and a geoprofessional.

- Aerial reconnaissance would be completed annually for the life of the Pipeline and stream crossings would be reviewed for major landscape changes such as channel migration and excessive erosion. Potential problem areas would be subsequently visited by PCGP and a geoprofessional.
- Quarterly site visits to all sites in the Orange management category (see GeoEngineers 2018a) for 2 years post construction to monitor revegetation success, structural stability of the restoration elements, any changes to fish passage potential resulting from the Pipeline, evidence of channel migration, erosion, head-cutting, or other stream channel movement that could influence stream or pipeline stability. Field measurements would be taken to monitor adjustments to the channel profile and cross sectional area.
- Annual site visits to 15 percent of all sites in the Blue management category and 100 percent of all sites in the Yellow management category (see GeoEngineers 2018a) for 2 years post construction to monitor revegetation success, structural stability of the restoration elements, any changes to fish passage potential resulting from the Pipeline, evidence of channel migration, erosion, head-cutting, or other stream channel movement that could influence stream or pipeline stability. Field measurements would be taken to monitor adjustments to the channel profile and cross-sectional area.
- Annual site visits to 50 percent of the sites in the Yellow and 100 percent of sites in the Orange management category (see GeoEngineers 2018a) by a geo-professional in Years 3, 5, 7, and 10 to monitor revegetation success, structural stability of the restoration elements, any changes to fish passage potential resulting from the project, evidence of channel migration, erosion, head-cutting, or other stream channel movement that could influence stream or pipeline stability. Field measurements would be taken to monitor adjustments to the channel profile and cross-sectional area.
- Observations would be made during all site visits on the effects of cattle/elk browsing on restoration success, and of impacts associated with recreational use.
- Revegetation planning along the right-of-way is detailed in the ECRP. The ECRP describes monitoring and performance standards for revegetation.
- Records would be maintained annually to document any significant hydrologic events (flow or rainfall) that occur in between site visits. This shall be done to better understand the site response to moderate or large flood events. As gauging stations are extremely limited over the majority of the crossings along the Pipeline route, rainfall records would be used to identify the potential flooding that may occur in between scheduled monitoring events. These climatic events would be considered during annual monitoring when evaluating site response.
- Unscheduled site visits may be completed at stream crossings on BLM and USFS jurisdiction following localized rainfall events exceeding a 25-year rainfall intensity to monitor revegetation success, structural stability of the restoration elements, any changes to fish passage potential resulting from the Pipeline, evidence of channel migration, erosion, head-cutting, or other stream channel movement that could influence stream or pipeline stability. Field measurements would be taken to monitor adjustments to the channel profile and cross-sectional area.
- Annual reporting in Years 1, 2, 3, 5, 7, and 10 following construction would be provided to outline observations of stream crossings and any remedial action taken to restore site conditions.

- Monitoring frequency and locations may be modified in response to demonstrating site restoration success in the Annual Monitoring reports.

Overall, these actions would reduce potential adverse effects from bank and bed stability to the listed shortnose sucker to unsubstantial levels.

3.5.6.5 Determination of Effects

Species

The Pipeline project **may affect** shortnose suckers because:

- shortnose suckers occur within the Upper Klamath River and Lost River Subbasins, which would be affected during construction of the proposed action.

While several Pipeline project actions are not likely to cause adverse effects, those resulting effects from Pipeline components that are **likely to adversely affect** shortnose suckers include:

- the possibility that shortnose suckers could occur within the Lost River when it would be crossed by the Pipeline and be affected by elevated suspended sediment levels;
- shortnose suckers could occur in 19 waterbodies crossed by dry open-cut construction in the Lake Ewauna-Klamath River watershed and in 13 waterbodies west of MP 214.38 (including the Lost River) crossed in the Mills Creek-Lost River watershed and be indirectly affected by elevated suspended sediment levels, streambank erosion and stability, and aquatic nuisance species introductions; and
- adults and juveniles subject to fish salvage within the isolated construction site at 31 ditches crossed by dry-open cuts and the Lost River could be affected if electroshocking is used and stressed if seining is used.

Critical Habitat

The Pipeline project is **not likely to adversely affect** designated critical habitat for the shortnose sucker because:

- HDD would avoid critical habitat in the Klamath River.

3.6 INVERTEBRATES

3.6.1 Vernal Pool Fairy Shrimp

Vernal pool fairy shrimp (*Branchinecta lynchi*) are small crustaceans, usually less than 2.4 cm (1 inch) long that live for only one season while there is water in a vernal pool. They can be found from Tulare County, California, north into Jackson County, Oregon.

3.6.1.1 Species Account and Critical Habitat

Status

On September 19, 1994, the final rule to list the vernal pool fairy shrimp as threatened was published in the Federal Register (FWS 1994b). In 2003, the FWS designated 839,460 acres of critical habitat for this species (FWS 2003a). In 2005, FWS (2005f) reevaluated the economic exclusions made in the 2003 final rule and excluded approximately 241,640 acres of land from the final 2003 designation for economic reasons. In 2006, the FWS produced species-specific unit descriptions and maps for the 597,821 acres of critical habitat designated for the vernal pool fairy shrimp, which included 7,574 acres of critical habitat in Jackson County, Oregon (FWS 2006e).

Threats

The FWS identified significant threats to vernal pool fairy shrimp by urbanization, conversion of wetlands to agriculture, indirect impacts from timber operations, grazing, mining, OHV use, road construction, right-of-way designation, hazard mitigation and post-disaster repairs, and other man-made changes in hydrologic patterns. In many cases, vernal pool complexes inhabited by the shrimp occurred on private land in areas of proposed or ongoing road, utility, residential, and commercial developments; the FWS was concerned that landowners could knowingly destroy vernal pool habitats (FWS 1994b, 2005e, and 2012h). Vernal pool contamination from runoff of surrounding areas may also injure or kill vernal pool fairy shrimp (FWS 2006e). Other factors noted as threats to vernal pool fairy shrimp in the final rule include stochastic events, which can have disproportionate effects on small, isolated populations and may result in local extirpations. Pools and pool complexes supporting vernal pool fairy shrimp are usually small, and unforeseen natural and human-caused catastrophic events threaten some sites (FWS 1994b).

In the 2007 five-year review of the vernal pool fairy shrimp, FWS determined threats to the species have not decreased since the time of listing in 1994 (FWS 2007g). The loss and modification of vernal pool habitat due to urban development, agricultural conversion, and infrastructure construction continue to be primary threats to the shrimp. For example, where the species is found in Southern Oregon (Medford Region), human population growth increased by 29.5 percent between 1990 and 2000 (FWS 2007g), although population growth slowed somewhat to 18.6 percent between 2000 and 2010 (GNRO 2012). FWS (2011f) has initiated another 5-year review for wildlife and plants in the Klamath Basin, including the vernal pool fairy shrimp.

Species Recovery

In November 2012, the FWS finalized a recovery plan for vernal pool species within the Rogue River and Illinois Valleys (FWS 2012h). The recovery plan (FWS 2012h) takes an ecosystem-based approach for recovery of three federally listed species, including the vernal pool fairy shrimp, and seven other rare species, and includes more Oregon-specific direction for recovery of the vernal pool fairy shrimp than previously provided in *The Recovery Plan for Vernal Pool Ecosystems of California and Southern Oregon* (FWS 2005e).

The recovery goal specific to the vernal pool fairy shrimp is (FWS 2012h):

- Recover the vernal pool fairy shrimp within its Klamath Mountains Recovery Zone (Agate Desert, Table Rocks, and White City area).

The recovery objectives included in the recovery plan are (FWS 2012h):

- Stabilize and protect populations of the vernal pool fairy shrimp within its Klamath Mountains Vernal Pool Region so further decline in species status and range are prevented.
- Minimize or eliminate the threats that caused the species to be listed and any newly identified threats.

- Conduct research necessary to refine downlisting and recovery criteria.
- Promote natural ecosystem processes and functions by protecting and conserving intact vernal pool-mounded prairie complexes and seasonally wet meadows within the recovery planning area.

The recovery plan includes the following delisting criteria for vernal pool fairy shrimp in the Klamath Mountain Region (FWS 2012h):

- At least 80 percent (9 of 11) of the occurrences within the Klamath Mountain Vernal Pool Region have been protected.
- At least 85 percent of suitable vernal pool habitat within the Klamath Mountain Vernal Pool Region has been protected.
- Develop and implement habitat management and monitoring plans that facilitate maintenance of vernal pool ecosystem function, especially hydrology function that contribute to population viability for all protected habitat.
- Cyst banking actions have been completed for the vernal pool fairy shrimp from at least one population in each of the three major core area groups (Agate Desert, Table Rocks, and White City).
- Status surveys, five-year status reviews, and population monitoring show vernal pool fairy shrimp populations within the Klamath Mountain Vernal Pool Region are viable (self-sustaining) and have been maintained (stable, increasing, or showing only minor declines from high population levels) for a 10-year monitoring period.

The recommended recovery and long-term conservation actions are (FWS 2012h):

- Protect vernal pool, wet meadow, and sloped mixed-conifer forest habitats.
- Manage, restore, and monitor vernal pool and wet meadow habitat.
- Conduct rangewide population status surveys.
- Conduct research essential to the conservation and recovery of the species.
- Enhance public awareness and participation in the recovery of the species.
- Develop a post-delisting monitoring plan.

Life History, Habitat Requirements, and Distribution

This freshwater crustacean is endemic to California and the Agate Desert of southern Oregon. The vernal pool fairy shrimp has an ephemeral life cycle and only inhabits vernal pools, or seasonal wetlands that fill with water during fall and winter rains. They are known to occupy a variety of vernal pool habitats, from small, clear, sandstone rock pools to large, turbid, alkaline, grassland valley floor pools. Vernal pools in which the shrimp has been collected have water temperatures ranging from 40 to 73°F, with low to moderate amounts of salinity or total dissolved solids (FWS 2005e). Individuals hatch from cysts during winter storms and require water temperatures of 50°F or lower to hatch. The time to maturity and reproduction is dependent on temperature, ranging between 18 and 147 days, with a mean of 39.7 days. The shrimp can die when water temperatures rise to about 75°F. Flooding and wildlife movement within and between vernal pool complexes allow the shrimp to disperse between individual pools, indicating that vernal pool fairy shrimp populations are defined by entire pool complexes, rather than individual pools (FWS 2007g).

Vernal pool fairy shrimp are found in 28 counties across the Central Valley and Coast ranges of California, and the inland valleys of southern California and southern Oregon (FWS 2005e). The shrimp was discovered in Jackson County, Oregon in 1998 at two distinct vernal pool habitats: on alluvial fan terraces associated with Agate-Winlo soil complexes in the Agate Desert, and in the Table Rocks area on Randcore-Shoat soil complexes underlain by lava bedrock (FWS 2005e). In Oregon, the vernal pool fairy shrimp is associated with the same vernal pool habitats as the large-flowered woolly meadowfoam and Cook's lomatium plant species (discussed below). The Agate Desert comprises the northern extent of the vernal pool fairy shrimp's range (FWS 2005e), where vernal pool fairy shrimp are located on non-Federal lands in three small Nature Conservancy Preserves totaling 297 acres, and within the 720-acre ODFW's Denman Wildlife Management Area (FWS 2007g).

Population Status

Actual numbers of fairy shrimp are not available, given their short life-span, and the nature of their reproduction (FWS 2012h); therefore, population (or species distribution) can only be inferred from the loss of vernal pool habitat. The historical distribution of vernal pool fairy shrimp is not known, especially in the Agate Desert in Oregon where it was recently discovered in 1998. However, it is estimated that vernal pool habitat in the Agate Desert has likely declined by 75 percent from historical extent (FWS 2007g). Additionally, over 40 percent of the vernal pool habitats remaining in Oregon have been degraded. Vernal pool fairy shrimp have been documented in 50 percent of the pools sampled in the Agate Desert Preserve, which is the highest percentage compared with other locales where the species is found (i.e., California) (FWS 2005e).

Critical Habitat

Within the Rogue Valley, 7,574 acres have been designated as critical habitat for the vernal pool fairy shrimp within the following quadrangles in Jackson County: Shady Cove, Eagle Point, Boswell Mountain, Brownsboro, and Sams Valley (FWS 2006e). When determining areas of critical habitat for the vernal pool fairy shrimp, FWS focused on the principal biological or physical PCEs that that are essential to the conservation of the species (FWS 2003c). Specifically, FWS (2003c) determined that two essential PCEs would apply to all critical habitat designated for vernal pool fairy shrimp:

1. vernal pools, swales, and other ephemeral wetland features of needed size and depth that become inundated during winter rains and hold water for the time necessary for life cycle completion, including but not limited to, Northern Hardpan, Northern Claypan, Northern Volcanic Mud Flow, and Northern Basalt Flow vernal pools; and,
2. the geographic, topographic, and edaphic features that support systems of hydrologically interconnected pools, swales, and other ephemeral wetlands and depressions within a matrix of surrounding uplands that together form what are known as vernal pool complexes.

3.6.1.2 Environmental Baseline

Analysis Area

Similar to the botanical analysis area that is described below for vernal pool plant species (see large-flowered woolly meadowfoam, section 3.7.3.2), the analysis area for the vernal pool fairy shrimp extends 250 feet each side of the Pipeline project (construction right-of-way, TEWAs) on lands that have potential habitat (Agate-Winlo soil complex) for the vernal pool fairy shrimp. Additionally, the analysis area extends 250 feet from the perimeter of four proposed pipe storage yards that are located within the Vernal Pool Complex – Agate Desert, Jackson County, Oregon where this species is known to occur, as shown in figure 3.6.1-1. This is a distance (250 feet) in which indirect effects from the Proposed Action could occur to vernal pools supporting this species (FWS 2011h).

Species Presence

Three proposed pipe storage yards (Burrill Lumber, Avenue F & 11th Street, and WC Short) are within proximity to federally-designated critical habitat units VERFS 3A and 3B in Denman Wildlife Management Area (WMA) and Agate Desert Preserve, and occur within the Agate-Winlo soil complex. A fourth proposed pipe storage yard (Rogue Aggregates) is 1 to 2 miles southwest/west of critical habitat units VERFS 4B and 3C (see figure 3.6.1-1) but does not occur within Agate-Winlo soil complex. Surveys within critical habitat units in the vicinity of proposed pipe storage yards have documented vernal pool fairy shrimp. The most recent observations were in 2004 and 2005 where 15 to 25 percent of the vernal pools sampled were occupied by fairy shrimp (ORBIC 2017b):

- VERFS 3A (Denman WMA):
  - 2004: eight pools occupied out of 53 sampled.
  - 2005: one pool occupied out of 31 sampled.
- VERFS 3B (Agate Desert Preserve, Denman WMA):
  - 2001: 11 occupied out of 43 sampled.
  - 2002: 11 occupied out of 62 sampled.
  - 2003: 35 pools occupied out of 99 sampled (complete habitat survey).
  - 2004: 12 pools occupied out of 25 sampled.
  - 2005: 2 occupied out of 8 sampled.
- VERFS 3C (Whetstone Savanna Preserve):
  - 2001: 1 pool occupied out of 3 sampled.
  - 2002: 75 occupied out of 271 sampled.
  - 2003: 28 occupied out of 80 sampled.
  - 2004: no survey.
  - 2005: 0 occupied out of 7 sampled.
- VERFS 4B (Lower Table Rock ACEC, Medford BLM): 3 individuals observed in 2004.

Project-Specific Surveys

In 2015, a survey protocol for Branchiopods, including vernal pool fairy shrimp, was published by the FWS (2015b). A complete survey consists of one wet season survey and one dry season survey conducted and completed within a 3-year period. Although potential vernal pool habitat that could be occupied by vernal pool fairy shrimp has been identified either through on-site surveys and/or off-site observations (table 3.6.1-1), no protocol vernal pool fairy shrimp surveys have been conducted for the Pipeline project because of landowner denial. Figure 3.6.1-3, identifies areas in the vicinity of the proposed pipe storage yards that have been evaluated for vernal pools on-site, areas that have been evaluated for habitat from off-site observations, and areas where vernal pool habitat was observed, and, where permitted, surveyed for large-flowered woolly meadowfoam or Cook's lomatium. At the time of ESA plant surveys, no surveys for vernal pool fairy shrimp were conducted and since ESA plant surveys, access to survey for vernal pool fairy shrimp, and other species has been denied.

In 2007, SBS identified vernal pool habitat in and near possible pipe storage yards in Jackson County that could provide habitat for two federally-listed plants (large-flowered woolly meadowfoam and Cook's lomatium, discussed in sections 3.7.3 and 3.7.4, respectively), as well as vernal pool fairy shrimp. Surveys for the federally-listed plants occurred in the proposed Burrill Lumber pipe yard and Rogue Aggregates pipe yard in 2007; no vernal pools were identified in the two proposed pipe storage yards, although approximately 4.4 acres of high quality suitable vernal pool habitat was observed 850 to 1,165 feet east of Burrill Lumber pipe storage yard where large-flowered woolly meadowfoam was documented (see figure 3.7.3-1 for large-flowered woolly meadowfoam; SBS 2008b). No surveys within Avenue F & 11th Street and WC Short pipe storage yards have been permitted by the landowner. Based on aerial photography and off-site observation in April 2018, Avenue F and 11th and WC Short pipe yard do not appear to contain vernal pools: Avenue F and 11th pipe yard is highly disturbed and graded, with railroad and docking faciltities located on the southern edge of the yard, and WC short pipe yard is an existing train yard that would assist moving and off-loading pipe. Although no vernal pools have been observed in Avenue F and 11th pipe yard, there is a long drainage ditch that runs along the northern edge of the pipe yard and paved Avenue F road and extends south along the western edge of the yard; the drainage has very little movement and could be considered low quality vernal pool habitat (approximately 0.45 acre) for the vernal pool fairy shrimp. No potential vernal pools have been identified in WC Short. In 2007, PCGP also identified suitable vernal pool habitat within two previously proposed pipe yards that are no longer proposed for use by the Pipeline project (approximately 10.5 acres of higher quality suitable vernal pool habitat located 100 feet south of Avenue F & 11th Street pipe storage yard and approximately 0.55 acre of higher quality vernal pool habitat located 860 feet north of Avenue F & 11th Street pipe storage yard, [SBS 2008b]). Although potentially suitable vernal pool habitat has been documented in proposed Jackson County pipe yards, no protocol surveys for vernal pool fairy shrimp are proposed. because PCGP would avoid using sections of the proposed pipe storage yards within 250 feet of any vernal pool habitat (extent of indirect effects), or PCGP would not pursue use of the pipe yard (see Conservation Measures, section 3.6.1.4).

In addition to potentially suitable vernal pool habitat in the vicinity of or within proposed pipe yards in Jackson County, nine vernal pools (approximately 0.2 acre) within and adjacent to the proposed right-of-way (MPs 145.30 to 145.40) were identified on private lands during botanical surveys conducted in 2007 and 2008. The vernal pools were surveyed for Cook's lomatium and large-flowered woolly meadowfoam in 2007 and 2008, and no plants were observed (SBS 2008b). Although this area is outside of the known range for vernal pool fairy shrimp, and the closest known occupied habitat is located approximately 8.2 miles west in critical habitat unit VERFS 2B, the vernal pools may provide suitable habitat for the vernal pool fairy shrimp because the pools occur within the appropriate soils type (Agate-Winlo) for vernal pool fairy shrimp (see figure 3.6.1-2). However, since botanical surveys in 2007 and 2008, no additional surveys have been permitted; therefore, no wetland delineations according to appropriate protocols have been completed to confirm vernal pool (wetland) presence within and adjacent to the construction right-of-way between MPs 145.30 and 145.40, and no protocol surveys for vernal pool fairy shrimp have occurred in these potentially suitable vernal pools. Once survey access is permitted, PCGP will conduct wetland delineations. If vernal pool habitat is confirmed during wetland delineations, PCGP would conduct surveys for vernal pool fairy shrimp following the 2015 FWS survey protocol by a certified surveyor – either two full wet season surveys completed within a 5-year period or two consecutive seasons of one full wet season survey and one dry season survey (or visa versa) (FWS 2015b). Surveys would not commence until a permit to survey is acquired from the FWS. PCGP will assume presence of vernal pool fairy shrimp until further surveys either determine no vernal pools present and/or protocol surveys for the fairy shrimp determine absence.

TABLE 3.6.1-1

Summary of Habitat Evaluated for Potential Vernal Pool Habitat within the Analysis Area [1]

General Landowner	Vernal Pool Habitat Status	Total Acres Surveyed [2]	Acres Surveyed [3]			Acres Not Surveyed [4]

1 Area evaluated for vernal pool dependent ESA species analyzed in this BA (large-flowered woolly meadowfoam, Cook's lomatium, and vernal pool fairy shrimp) included habitat in Agate-Winlo soil complex, within 250 feet of proposed Pipeline components located in Jackson County; area was evaluated on-site, where permitted, or off-site from existing roads and/or 2016 aerial photography to identify vernal pool habitat. Surveys for botanical species occurred in vernal pools documented during on-site evaluations; no surveys have been conducted to-date for vernal pool fairy shrimp.

2 Acres provided in this column considers all on-site evaluations/surveys to-date, including areas that have been subsequently rerouted or dropped (i.e., pipe yards) since habitat evaluations and surveys were initiated in 2007. Surveys for botanical species occurred within vernal pool habitat.

3 Acres Surveyed: includes area within 250-feet of the Pipeline (right-of-way and pipe yards) that had habitat evaluated on-site for vernal pool habitat. Protocol surveys were conducted within identified vernal pool habitat for ESA botanical species (large-flowered woolly meadowfoam and Cook's lomatium); no surveys have been conducted to-date for vernal pool fairy shrimp.

4 Acres Not Surveyed: includes areas evaluated off-site that were either denied access or are outside of the targeted survey area (Jackson County pipe yards); the majority of habitat that occurs within 250 feet of Jackson County pipe yards is industrial. Off-site observations identified potentially suitable vernal pool habitat (0.48 acre) that would require surveys once access is permitted; all other habitat is not suitable for ESA species. Area (acres) does not include suitable vernal pool habitat that occurs within 250 feet of Burrill Lumber pipe yard within Ken Denman State Game Management Reserve; habitat is located across Agate Road (paved and raised) from Burrill Lumber pipe yard (9.45 acres).

5 Project includes: right-of-way, temporary extra work area, and pipe yards.

6 Buffer (botanical analysis area) includes area within 250-foot buffer around the pipe yards in Jackson County, as well as between MPs 145.3 and 145.4 along the Pipeline right-of-way that crosses Agate-Winlo soil complex.

7 Jackson County Pipe Storage Yards considered: Burrill Lumber, Ave F and 11th Street, WC Short, and Rogue Aggregates.

8 Vernal pool habitat observed during on-site and off-site evaluations: includes all vernal pool wetlands documented, including ditches with vernal pool characteristics.

9 Vernal Pool Complex includes upland habitat within 100 feet of vernal pool habitat (see footnote #8).

Note: most area that remains to be surveyed occurs on private lands; surveys would continue as access becomes available.

Critical Habitat

Four pipe storage yards (Rogue Aggregates, Burrill Lumber, Ave F & 11th Street, and WC Short) are proposed within Eagle Point and Sams Valley quadrangles where ten designated critical habitat units are within 3 miles of the proposed yards. Figure 3.6.1-1 identifies locations of proposed pipe storage yards in relation to federally-designated critical habitats for vernal pool fairy shrimp.

One critical habitat unit (VERFS 3A), which is centered on the Ken Denman WMA, was delineated such that it crosses over the top of Agate Road (paved surface) and encompasses a 25-foot wide band of previously disturbed areas used for lumber processing within the western portion of proposed Burrill Lumber pipe storage yard. However, FWS (2017e) indicated that CHU VERFS 3A was incorrectly delineated and should be delineated to the western edge of Agate Road right-of-way and not cross over the road and into Burrill Lumber property. Burrill Lumber pipe storage yard and its surrounding was surveyed for vernal pool habitat in 2007; no suitable habitat for vernal pool fairy shrimp was observed within the proposed Burrill Lumber pipe storage area (SBS 2008b). Survey data reported by ORBIC (2017b) documented vernal pool fairy shrimp within suitable habitats in critical habitat unit VERFS 3A on the western side of Agate Road, but no occupied habitat occurs within the proposed boundaries of the Burrill Lumber pipe yard. Another critical habitat unit (VERFS 3B) is in the vicinity of three proposed pipe storage yards (Burrill Lumber, Avenue F & 11th Street and WC Short), ranging from 915 feet to 2,500 feet. Two other critical habitat units (VERFS 4B and VERFS 3C) occur within 1 to 2 miles of Rogue Aggregates pipe storage yards. Survey data reported by ORBIC (2017b) have documented vernal pool fairy shrimp in all critical habitat units in the vicinity of proposed pipe storage yards.

3.6.1.3 Effects of the Proposed Action

Direct and Indirect Effects

Because of the rarity of vernal pool fairy shrimp, any direct impact resulting in species take or habitat loss would be a significant hindrance to its recovery. Direct effects to the shrimp and its habitat could be expected in vernal pools and upland habitat 100 feet from delineated vernal pools (vernal pool complex; FWS 2011h). Examples of potential direct impacts could include possible disturbance to pools from driving or storing equipment or pipes near or on vernal pools or wetlands, pipeline construction through vernal pools, or draining or modifying hydrology to pools containing live shrimp or their cysts. Those actions could directly destroy or disturb vernal pool fairy shrimp cysts (during the dry season) or live shrimp (during the wet season). Proposed pipe storage yards in Jackson County are located on lands where past heavy industrial uses have occurred. Since no vernal pool habitat has been documented in surveyed Jackson County proposed pipe storage yards, and since vernal pool habitats would be avoided in unsurveyed pipe storage yards by at least 250 feet (see Conservation Measures, below), no vernal pool fairy shrimp or potentially suitable vernal pool habitat would be directly impacted from use of pipe storage yards. On the other hand, direct impact to vernal pool fairy shrimp could occur if fairy shrimp or hibernating cysts are present in nine vernal pools within and adjacent to the Pipeline right-of-way (MPs 145.34 to 145.40). Although the vernal pools identified along the right-of-way are outside the known range of vernal pool fairy shrimp, these pools may support vernal pool fairy shrimp since they are within the soils (Agate-Winlo) appropriate for this species (see figure 3.6.1-2). Therefore, PCGP will assume presence of vernal pool fairy shrimp within the boundaries of vernal pools unless future wetland delineations determine no vernal pool presence and/or protocol surveys for the species determine fairy shrimp absence.

Indirect effects to vernal pool fairy shrimp and their habitat could occur with increased road use for access to pipe storage yards, truck and heavy equipment use within pipe yards, as well as construction and restoration activities where these activities occur near or are adjacent to suitable or potentially suitable habitat. Increased dust deposition in vernal pool habitats could affect vegetation and vernal pool physical or chemical properties (pH, water quality, turbidity, sedimentation, temperature). Soil compaction and sediment mobilization during use of pipe storage yards or construction of the Pipeline along the right-of-way may indirectly affect hydrology upon which vernal pools and associated vegetation are dependent. Indirect effects to hydrology could occur if within 250 feet of proposed activities (FWS 2011h). Run-off from proposed pipe storage yards may result in the delivery of harmful elements to habitats, including increased sediment loading, since pipe yards were often previously used for industrial or timber processing, and soils may contain residual components which could negatively affect fairy shrimp or their habitats. Also, road use adjacent to or near suitable or potentially suitable vernal pool fairy shrimp habitat may increase the risk of introduction of non-native, weedy species that could compete with native plant species associated with the vernal pool fairy shrimp. Construction of the Pipeline near potential suitable vernal pools near MPs 145.34 and 145.40 could also indirectly affect this species, if vernal pool wetlands (and vernal pool complex [upland habitat within 100 feet of vernal pool wetlands]) are present within 250 feet of Pipeline construction.

Based on the above analysis, construction and operation of the Pipeline between MPs 145.3 and 145.4 may directly or indirectly affect fairy shrimp associated with up to 0.19 acre of vernal pool wetlands (and 4.59 acres of vernal pool complex [upland habitat within 100 feet of vernal pool wetlands]) located within 250 feet of proposed Pipeline activities. Of this acreage, 0.03 acre of vernal pool habitat (and 1.18 acres of vernal pool complex) would be directly affected within the Pipeline right-of-way (see table 3.6.1-2). PCGP will implement a number of BMPs to minimize direct and indirect potential impacts to vernal pool wetlands during Pipeline construction (see section 3.6.1.4, Conservation Measures).

TABLE 3.6.1-2

Vernal Pool Habitat Directly / Indirectly Affected by the Pipeline Project within 250 feet of the Pipeline Right-of-Way (MPs 145.3 - 145.4)

Vernal Pool Complex	**Pipeline Right-of-Way**	**Buffer (250 feet)**	**Total**
Vernal Pool / Wetlands	0.03	0.16	0.19
Upland Habitat (100-foot Buffer)	1.18	3.41	4.59
Total	*1.21*	*3.57*	*4.78*

No direct or indirect effects to potential vernal pools are expected from use of proposed pipe storage yards in Jackson County, including 0.48 acre of potential vernal pool wetlands (and 15.55 acres of vernal pool complex) identified from off-site observations within or

adjacent to proposed pipe yards (see table 3.6.1-1). Within the vicinity of Jackson County pipe yards, vernal pool habitat is within 250 feet of Burrill Lumber pipe yard and Avenue F & 11th Street pipe yard; however, all vernal pool habitat is either separated by an existing paved access road (west of Burrill Lumber) or an existing railroad bed (south of Avenue F & 11th Street), and activities within proposed pipe yards would not be expected to adversely affect vernal pool wetlands. Although a drainage has been identified on the north and west edges of Avenue F & 11th Street pipe yard, Pipeline use, if any, would be located farther than 250 feet from the potential vernal pool habitat. Although no direct or indirect effects from use of pipe yards by the Pipeline project would be expected, road use adjacent to or near suitable habitat could increase the risk of introduction or spread of noxious weeds (see Conservation Measures, section 3.6.1.4).Cumulative Effects

Additional projects within the analysis area are anticipated as human population growth continues in the region. Residential, commercial, and industrial development are likely to occur in the foreseeable future. Human population in Jackson County grew a little more than 5 percent between 2010 and 2016. The Jackson County planning department is currently reviewing multiple permit applicantions for reasonably foreseeable projects proposed within and around the core vernal pool areas near the Project. Although Jackson County was not able to provide a comprehensive list or details regarding these reasonably foreseeable projects, development in and around vernal pool fairy shrimp habitat could be detrimental to the species if the proper conservation measures are not implemented. However, any developments that could potentially affect vernal pool habitat would be required to comply with COE and Oregon Department of State Lands requirements, which would reduce the likelihood of cumulative negative effects to this species and their habitats.

Critical Habitat

The FWS (2003c) identified two PCEs when designating critical habitat that considers soil moisture and aquatic environment required, as well as upland areas that may be associated with maintaining the aquatic and drying phases of the vernal pool or complexes. Vernal pools on the Agate Desert Preserve in the vicinity of proposed pipe storage yards in Jackson County, Oregon, generally consist of remnant parcels of disturbed or degraded vernal pool habitat and are threatened by indirect effects of adjacent land use, including alteration of hydrology (FWS 2007g). Williamson et al. (2005, cited in FWS 2007g) indicate that surface or subsurface changes to water flow could have deleterious effects on vernal pool ecosystem function protected areas within or adjacent to altered watersheds. Rains et al. (2006, cited in FWS 2007g) also indicated that small changes in local land use may have considerable impacts on vernal pools and their hydrology. Hydrology can also be altered by non-native grasses that occur commonly in vernal pool complexes.

One proposed pipe storage yard (Burrill Lumber) is located within the far eastern edge of FWS-delineated critical habitat unit VERFS 3A; however, FWS (2017e) indicated that this critical habitat unit was incorrectly delineated and its eastern border should have been delineated on the western edge of Agate Road right-of-way. No other pipe yards are located within 250 feet (distance of potential indirect effects to vernal pool wetlands) of delineated critical habitat (see figure 3.6.1-1). No direct impacts from the proposed action to vernal pool fairy shrimp critical habitat are expected since equipment and pipe storage would not occur on pools or wetlands (or vernal pool complex – upland habitat within 100 feet of vernal pool wetlands) in delineated critical habitat, nor would traffic to and from the pipe storage yards drive near or on pools within the designated critical habitat units.

Because the Burrill Lumber pipe yard location has been surveyed by qualified biologists, and they have documented that there is no suitable or potentially suitable habitat within the proposed Burrill Lumber pipe yard, there would be no direct impacts from the proposed action to vernal pool fairy shrimp critical habitat since equipment and pipe storage would not occur near or on pools or wetlands, nor would traffic to and from the pipe storage yards drive near or on pools within the designated critical habitat units. Possible indirect effects to the critical habitat units may occur as a result of increased dust deposition and stormwater runoff, and the potential for an increased risk of accidental spills in areas that are adjacent to the critical habitat units. Increased fugitive dust might impact vernal pool habitat within VERFS 3A as dust settles, affecting associated vegetation and vernal pool physical or chemical properties (pH, water quality, turbidity, sedimentation, and temperature). Indirect effects to hydrology within 250 feet of suitable or potentially suitable vernal pool habitat within VERFS 3A is not expected since existing, paved Agate Road occurs between currently disturbed Burrill Lumber pipe yard and VERFS 3A. However, use of Agate Road adjacent to the critical habitat unit and use of Burrill Lumber pipe storage yard may increase the introduction of non-native, weedy species.

Applying conservation measures identified below (section 3.6.1.4) and use/alteration/restoration of pipe storage yards should minimize effects to vernal pool habitat and/or vernal pool fairy shrimp within VERFS 3A.

3.6.1.4 Conservation Measures

PCGP has eliminated from further consideration the following previously proposed pipe storage yards to avoid potential effects to high-quality vernal pool habitat: Avenue C and 7th Street-Elite Cabinet & Door, Medford Industrial Park and a portion of the previously delineated Burrill Lumber yard that included high quality vernal pool habitat east of the currently proposed yard. To avoid impacts to potential vernal pool habitat along the northern and western edge of Avenue F and 11th Street pipe yard, PCGP would avoid using portions of Avenue F and 11th Street pipe storage yard within 250 feet of potential vernal pool habitat (boundary of indirect effects) or no longer pursue use of the pipe yard, similar to actions taken in previously proposed pipe storage yards with vernal pool habitat.

When survey access is permitted along the right-of-way between MPs 145.30 and 145.40, PCGP would conduct wetland delineations according to appropriate protocols to confirm vernal pool (wetland) presence/absence. If wetland delineations confirm the presence of vernal pools along the right-of-way, PCGP would have a certified surveyor conduct surveys for vernal pool fairy shrimp following the 2015 FWS vernal pool fairy shrimp survey protocol (FWS 2015b). Surveys would not commence until a permit for surveys is obtained from the FWS. If this species is identified during survey efforts, or if vernal pool fairy shrimp survey efforts do not occur at this location due to construction time constraints, PCGP would evaluate a potential reroute to avoid vernal pools by at least 250 feet with the landowner. If a reroute between MPs 145.30 and 145.40 is not possible, PCGP would discuss potential mitigation options with FWS to offset direct and indirect effects from Pipeline construction to potential vernal pool fairy shrimp within vernal pools (0.19 acre) (and vernal pool complex [4.59 acres] - upland habitat within 100 feet of vernal pools) within 250 feet of the Pipeline (see table 3.6.1-2). Additionally, PCGP would erect a silt fence on the west side of the right-of-way within 250 feet of the vernal pools located between MPs 145.27 and 145.44 to avoid or minimize any potential effects to surface drainage or current hydrologic conditions (FWS 2012h) and to prevent construction personnel and vehicles from incidentally affecting the vernal pools complex outside of the permitted right-of-way.

To minimize potential effects to vernal pools within 250 feet of the Pipeline project, PCGP would control fugitive dust along the construction right-of-way and at proposed pipe storage yards, as described in the Air, Noise and Fugitive Dust Control Plan (see appendix B to the POD). Applying water to pipe yards and along the right-of-way near MPs 145.34 to 145.40 would reduce the potential for adverse effects from fugitive dust to vernal pool habitat that is in proximity to the Pipeline. PCGP would also implement site-appropriate BMPs outlined in the ECRP (see appendix F) to mitigate the potential for increased sediment mobilization, thereby reducing any potential impacts to water quality in vernal pools. To minimize the potential spread of invasive species to vernal pool habitats, PCGP would implement BMPs outlined in the Integrated Pest Management Plan (see appendix N to the POD). Within 250 feet of vernal pools located in Agate-Winlo soils complex, all treatment for control of noxious and invasive weeds would occur through hand pulling or other approved hand-operated mechanical methods. Further, as per FERC requirements, all on-site construction personnel would receive instruction regarding the presence of listed species and the importance of and methods for avoiding impacts to this species and its habitat.

3.6.1.5 Determination of Effects

Species

The Project **may affect** vernal pool fairy shrimp because:

- potentially suitable habitat for vernal pool fairy shrimp has been identified in the vicinity of four proposed Jackson County pipe storage yards, as well as within and adjacent to the Pipeline right-of-way from MPs 145.34 and 145.40.

The Project is **likely to adversely affect** vernal pool fairy shrimp because:

- direct or indirect impacts to vernal pool fairy shrimp is possible from Pipeline construction within or adjacent to nine potentially suitable vernal pools identified between MPs 145.34 to 145.40 within Agate-Winlo soils, if the species is present.

Critical Habitat

A **not likely to adversely affect** determination is warranted for vernal pool fairy shrimp critical habitat because:

- although proposed Burrill Lumber pipe yard occurs within 250 feet from a designated vernal pool fairy shrimp critical habitat unit (VERFS 3A), it is separated from the critical habitat unit by Agate Road, which is a two-lane paved road that acts as a barrier to hydrologic connectivity that is considered a definitive boundary to the area of effects;
- Burrill Lumber pipe yard has been previously disturbed, and additional surface disturbances and/or soil compaction by heavy machinery from use within Burrill Lumber pipe storage yard should be minimal. Also, Agate Road is located between Burrill Lumber pipe yard and critical habitat unit VERFS 3A, which is raised and paved, and

would serve as an existing barrier between the pipe yard and critical habitat unit. Therefore, use of the Burrill Lumber pipe storage yard is not expected to adversely modify geographic, topographic, and edaphic features potentially within 250 feet of the yard that support systems of hydrologically interconnected pools, swales, and other ephemeral wetlands and depressions within the matrix of surrounding uplands (PCE 2); and

- proposed conservation measures would reduce and mitigate the potential for increased sediment mobilization, increased fugitive dust, and the potential spread of invasive species to suitable vernal pool habitats.

3.7 PLANTS

3.7.1 Applegate's Milk-vetch

The Applegate's milk-vetch (*Astragalus applegatei*) is a slender perennial of the pea (Fabaceae) family. It is known only in Klamath County, Oregon. The plant can be found in flat-lying, seasonally moist, strongly alkaline soils with sparse native grasses dominated by greasewood (*Sarcobatus vermiculatus*).

3.7.1.1 Species Account and Critical Habitat

Status

Applegate's milk-vetch was listed as endangered on July 28, 1993 (FWS 1993c). It was believed to be extinct until its rediscovery in 1983 and at the time of listing was only known from two extant sites.

Threats

In the five-year review of Applegate's milk-vetch, FWS identified continued destruction, modification, or curtailment of its habitat or range due to urban and commercial development, and loss of habitat through competition with non-native weeds as the principal threats to the species survival (FWS 2009c). According to the FWS' *Applegate's Milk-Vetch Recovery Plan* (1998b), habitat loss and modification due to development and hydrologic manipulation also continue to threaten Applegate's milk-vetch. Portions of the Ewauna Flat population have been destroyed by urban development on private land and more are at risk because they occupy industrially-zoned properties. Construction of ditches and dikes in the Klamath Basin alter the hydrologic character of Applegate's milk-vetch habitat. The FWS concluded that these changes could result in lethally dry conditions, or may indirectly impact the species by introducing drought-tolerant and exotic plants (FWS 1998b).

Several other factors were identified in the decision to list the Applegate's milk-vetch. Overutilization for commercial, recreational, and scientific purposes was a potential threat at the time of listing because the known locations of these rare plants are easily accessible by road. FWS also identified predation from rabbits and cattle as obstacles to the plant's survival (FWS 1993c). Additionally, because of the small number of populations, a limited gene pool, and the small number of plants in the total population, the FWS determined that the potential for extinction from stochastic events (fires or floods) is a threat to the species (FWS 1993c).

Species Recovery

The *Applegate's Milk-Vetch Recovery Plan* was drafted with the goal to increase the stability of Applegate's milk-vetch so that it can be down-listed. The two main objectives of the recovery plan (FWS 1998b) are to:

- increase the species' representation to at least six areas with a minimum of two populations occurring at each of the three recovery areas identified in the plan; and
- develop management strategies that provide for long-term stability.

To achieve the two objectives, the recovery plan recommends the following actions:

- conserve natural and introduced Applegate's milk-vetch populations;
- develop long-term, off-site seed storage;
- conduct research on population sustainability, population establishment and augmentation techniques, efficacy of habitat management strategies, and the plant's edaphic and hydrologic requirements; and
- develop and implement an outreach program.

The five-year review of Applegate's milk-vetch (FWS 2009d) reported that since the recovery plan was published, three new occurrences of Applegate's milk-vetch have been found. The review states that recovery criteria should be modified to include opportunities to achieve self-sustaining populations at the newly discovered sites. Specifically, the five-year review suggests that Applegate's milk-vetch would be considered for downlisting to threatened status when (FWS 2009d):

- *At least two natural and/or introduced self-sustaining populations are preserved in each of the three recovery areas (Ewauna Flat, Miller Island, and Worden), for a total of six or more populations in habitat permanently secured and managed for the benefit of the species. A minimum of 4,500 reproductive plants is needed for a recovery area to meet the downlisting threshold. Self-sustaining populations are defined as containing a minimum of 1,500 reproductive plants, plus sufficient individuals in younger age classes to suggest population stability or growth.*

Applegate's milk-vetch population establishment techniques have not been successful and additional transplantation methods will continue to be investigated (Gisler 2002; ORBIC 2007). FWS also recommended further research on the impacts of weed competition on Applegate's milk-vetch, pollination and self-fertilization processes, and herbivory and predation processes (FWS 1998b).

Life History, Habitat Requirements, and Distribution

Soils in typical Applegate's milk-vetch habitats are characterized as being gray in color, slightly alkaline, with a shallow water table and groundwater with a relatively high salinity due to periodic flooding and evaporation (TNC 1999). Applegate's milk-vetch grows only in flat-lying, seasonally moist, alkaline soils with underlying clay hardpans. The underlying clay hardpans provide seasonal soil moisture, saturation and retention, forming a hydrological regime which may be a requirement for dry summer months when flowering and seeding occur (FWS 1998d). Alkaline soils may support mycorrhizal fungi and rhizobium bacteria beneficial to the survival and growth of the milk-vetch (FWS 1998d). As with other plants growing under extreme conditions of alkalinity, heavy metals, and/or salinity, Applegate's milk-vetch may benefit from alkaline soils to help reduce competition from other species (FWS 1998d).

The vegetative community in which Applegate's milk-vetch sites occurs is classified as interior alkali grassland (TNC 1999). The species' habitat was historically characterized by sparse, native bunch grasses and patches of bare soil, allowing for some seed dispersal by wind. Today, dense coverage of the habitat by introduced grasses and weeds means seed dispersal is highly localized, with most seedling establishment found adjacent to mature plants (FWS 1998d). Flowering usually begins in early June and ends in August. Reproduction takes place exclusively by seeds, which are shed soon after flowering. Pollination is thought to be mediated by butterflies (e.g., *Lycaedes argyrognomon* and Melissa blue butterfly, *Plebejus melissa*) and polylectic bees (Yamamoto 1985), although the plant is also capable of seed production through self-fertilization.

Since the publication of the recovery plan in 1998, there have been numerous cooperative efforts made by Oregon Department of Agriculture, ORBIC, TNC, the FWS, and private landowners to conduct inventories for Applegate's milk-vetch throughout most of its historical range. It is known to occur only in the Lower Klamath Basin (the plain containing Lower Klamath Lake), near the city of Klamath Falls in southern Oregon. Three new sites discovered since publication of the recovery plan include the Collins tract, the Klamath Falls Airport, and the Washburn Way-Railroad track (FWS 2009d), and plants have been discovered in two other areas within the Lower Klamath Basin [Klamath West (2009) and Woods Line State Trail (2013)] (ORBIC 2017b).

Population Status

At the time of listing, this species was known from only two extant sites (Miller Island and Ewauna Flat) that supported approximately 30,000 plants and one historical site (Keno; FWS 1993c). One additional site (Klamath Falls) had been documented shortly after the listing, but this site was extirpated in 1992 prior to the completion of the 1998 recovery plan and lumped together with the Ewauna Flat population (FWS 2009d). In the 1998 recovery plan, there were three known extant populations in Klamath County, numbering about 12,000 plants (FWS 1998d): the Ewuana Flat population contained an estimated 11,500 individuals within three sub-populations, the Miller Island population contained less than 500 plants within four small sub-populations on approximately one acre, and a third population discovered in 1997 (Worden) included three plants (FWS 1998d). Since the recovery plan, three additional sites were discovered (Collins Tract, Klamath Falls Airport, and Washburn Way-Railroad) for a total of six known extant sites and an estimate of 33,800 plants (FWS 2009d). The largest population is located near the Klamath Falls Airport where more recent surveys in 2012 and 2013 documented an estimated 24,000 plants (USDOT 2015). ORBIC (2017b) identified two additional areas where Applegate's milkvetch had not been previously documented: 1) approximately 1,260 plants documented by FWS and TNC in 2009 on either side of the railroad tracks on the west side of Klamath River (Mallard), and 2) 100 to 200 or more plants documented in an abandoned railroad right-of-way (OC&E Woods Line State Trail) in 2013. These two areas represent new populations (sites), bringing the known current total of extant populations to eight. Table 3.7.1-1 provides a summary of Applegate's population status at the time of federal listing in 1993, the draft recovery plan in 1998, and latest available status (FWS 2009d and USDOT 2015).

Local populations (table 3.7.1-1) range from nine plants in the Worden site to thousands of plants in two sites (Klamath Airport and Collins Tract sites). Multi-year trend data have been collected at The Nature Conservancy Preserve site near Ewauna Lake. These data document a downward decline in the subpopulation from 30,000 to approximately 2,200 plants in 2008 (FWS 2009d).

TABLE 3.7.1-1

Summary of Applegate's Milk-vetch Population Status by Site at the Time of Federal Listing (1993), Publication of the Recovery Plan (1998), and Most Recent

Site Name	Ownership	Number of Plants at Time of Listing (1993)	Number of Plants at Time of Recovery Plan (1998)	Most Recent	Current Status
Ewauana Flat Preserve	The Nature Conservancy	Up to 30,000 plants	Approximately 11,500 plants	Approximately 2,198 plants	Declining
OC&E Woods Line State Trail	State of Oregon	Undiscovered	Undiscovered	100 to 200+ plants	Unknown
Mallard	City of Klamath Falls & Private	Undiscovered	Undiscovered	675 plants	Unknown
Miller Island	State of Oregon	30 to 80 plants	Fewer than 500 plants	112 plants	Unknown
Keno	Private	Historical (extirpated)	Historical (extirpated)	Historical (extirpated)	Extirpated
Worden	Private	Undiscovered	3 plants	9 plants	Unknown
Collins Tract	Private	Undiscovered	Undiscovered	10,143 plants	Unknown
Klamath Falls Airport	City of Klamath Falls	Undiscovered	Undiscovered	24,000 plants	Unknown
Washburn Way-Railroad	Private	Undiscovered	Undiscovered	307 plants	Unknown
Klamath Falls	Private	Believed to have been extirpated	13 plants found in 1994	Extirpated	Extirpated

Critical Habitat

Critical habitat has not been designated for Applegate's milk-vetch.

3.7.1.2 Environmental Baseline

Analysis Area

The botanical analysis area extends to 30 meters (98 feet) each side of the Pipeline project (construction right-of-way, TEWAs, UCSAs, rock source and disposal sites, and proposed storage yards) on lands that have potential habitat for listed plant species. This area generally corresponds to the extent of the area surveyed for sensitive and listed plant species during surveys conducted between 2007 and 2017 and correlates to a distance that indirect effects to plants would be expected. Survey for this species targeted all flat areas with moist alkaline soils with native grasses and greasewood (at least 100 feet from habitat removal on federal lands and at least 50 feet from habitat removal on non-federal, private lands).

Species Presence

The Pipeline project is located within known or historic Applegate's milk-vetch range between MPs 191.20 to 214.30 within the Lake Ewauna-Klamath River 5th field watershed. Herbarium records indicate that a known historical population (1937), now presumed extirpated (ORBIC 2017b), occurred near the Pipeline project (MP 191.2 to MP 191.97; see the Keno Site included in table 3.7.1-1). Efforts to relocate this species in the historic area have been unsuccessful (FWS 1998d; SBS 2008a and 2017a). The Pipeline project also occurs within the Collins Tract population between MPs 195.35 and 196.50. Plants have been documented north and south of the proposed Pipeline (MP 195.5 to MP 196.7) (ORBIC 2017b; SBS 2008a and 2017a). Estimates of more than 10,000 plants at multiple sites in the Collins Tract area were made in 2008, extending from across the Klamath River from and adjacent to the Lower Klamath National Wildlife Refuge and State Wildlife Area (FWS 2009d; ORBIC 2017b). Botanical surveys conducted by PCGP between 2007 and 2008 located three new sites for Applegate's milk-vetch in the Collins Tract (SBS 2008a), discussed further, below. The Collins Tract site was revisited in 2010 by FWS and only one sub-population was documented in the area with 21 plants (ORBIC 2017b).

At another location within and adjacent to proposed Klamath Falls Memorial Drive 2 pipe storage yard, the FWS and The Nature Conservancy documented approximately 1,260 plants in 2009 near the Klamath River on either side of railroad tracks (survey site Klamath West; ORBIC 2017b).

Project-Specific Surveys

Habitat Surveyed. Prior to beginning field surveys in 2007 for the Pipeline project, botanists with SBS conducted a habitat review to identify potential habitat and delineate survey areas for Applegate's milk-vetch within the botanical analysis area, including existing roads identified for access to the construction right-of-way. Aerial photographs and knowledge of regional landscape and biological features (soils, geology, topography, elevation, target species habitat, and associated plant community habitat) were used to determine potential habitat for Applegate's milk-vetch. These same methods were applied to determine areas of suitable habitat in new locations where the proposed right-of-way has been relocated since 2007.

Surveys were conducted for this species where survey permission was granted within the vicinity of the Pipeline project (within at least 50 or 100 feet of the Pipeline project on non-federal and federal lands, respectively and where permitted) and along proposed access roads (within at least 50 feet of access roads where road improvements are proposed and surveys permitted). Most surveys were conducted in 2007 and 2008, but additional surveys have been conducted since 2008 in areas of reroutes, minor route adjustments, and areas with survey permission. Areas where Applegate's milkvetch were documented during previous Pipeline survey efforts were also resurveyed. Surveys have continued in 2018 and the data are currently under review.

Overall, 865.56 acres have been surveyed by the Applicant from 2007 through 2017 for Applegate's milkvetch within the vicinity of the proposed Pipeline, including previously proposed routes and project components, alternate routes, and along access roads that are no longer considered for the Pipeline project. Approximately 726.78 acres have been identified as potential habitat requiring surveys within the botanical analysis area (30 meters of the Pipeline project) between MPs 191.70 and 214.30 in Klamath County, including habitat identified in and around proposed pipe storage yards north of the Pipeline along the Klamath River and near the Klamath Airport (table 3.7.1-2). Of this habitat, access was granted to about 553.14 acres

(307.47 acres within the Pipeline right-of-way), of which 109.05 acres (61.82 acres within the Pipeline right-of-way) were considered suitable habitat for Applegate's milk-vetch.

[1] Acres provided in this column considers all surveys to-date (through 2017), including areas that have been subsequently rerouted or dropped (i.e., pipe yards) since surveys were initiated in 2007.
[2] Project includes: right-of-way, temporary extra work area, uncleared storage area, rock storage, pipe yards, aboveground facilities.
[3] Buffer (botanical analysis area) includes area within 30 meters (98 feet) of habitat removal and within 50 feet either side of an existing access road identified with possible road improvements.
[4] Areas not surveyed are either denied access or were not surveyed because of recent modification in Proposed Route that occurred after the flowering season, as well as areas outside of the targeted survey area (i.e., 30-meter analysis area vs. 50-foot targeted survey area on non-federal lands). "Not Habitat" was determined from adjacent survey parcel information, aerial photography, or "drive-by;" no surveys would be necessary and acres are not included.

Note: Surveys have continued in 2018 and the data are currently under review. Most area that remains to be surveyed occurs on private lands; surveys would continue as access becomes available.

Approximately 173.64 acres (76.95 acres within the Pipeline project) of potentially suitable habitat for Applegate's milk-vetch have not been surveyed within the botanical analysis area either where survey access has not been granted or within areas of recent Pipeline modifications. PCGP would continue to survey habitat where permission is granted. Since permission to survey on non-federal lands targeted an area of at least 50 feet from the Pipeline project, it is very likely that habitat within the "buffer" (30-meter botanical analysis) area would likely not be surveyed. Where survey access has been denied, PCGP would conduct surveys in suitable habitat within the Pipeline project prior to construction. If the assumption is made that a similar percent of this area is suitable (compared to the areas where surveys have been completed in the botanical analysis area), then approximately 34.21 acres of unsurveyed habitat within the botanical analysis (19.7 percent of 76.95 acres, or 15 acres within the Pipeline right-of-way) are likely suitable Applegate's milk-vetch habitat.

Survey Results. Applegate's milk-vetch plants were documented by SBS (and FWS) during surveys in 2008 in the vicinity of MPs 195.5 and 196.6; all observations were associated with the previously documented Collins Tract population. Applegate's milk-vetch plants within the Collins Tract population were first discovered in 1998 (table 3.7.1-1). Additional field surveys since 1998, including efforts by PCGP, discovered several additional sub-populations that increased the known number of plants and occupied habitat at the Collins Tract site: in 2007 ORBIC discovered two large sub-populations, each several acres in size (Roninger 2008), and expanded survey efforts by FWS and SBS in 2008 discovered several sub-populations clusters (which includes the adjacent landowner JWTR LLC) (Roninger 2008; SBS 2008b). In 2008, the entire Collins Tract was found to contain 10,133 plants within 19 sub-populations on 32.3 acres within a larger 250-acre area, which, by Recovery Plan standards (see FWS 1998d), would qualify as a self-sustaining population (see figure 3.7.1-1). The 19 individual sub-population clusters ranged from a single plant to thousands of plants. The Applegate's milk-vetch located at the Collins Tract site were in habitat slightly different than other known populations: soil was less alkaline and not associated with the usual vegetative structure (i.e., very little or no rabbitbrush present). Also, weeds present within this area include cheatgrass, mouse barley, and sweet clover (SBS 2008b). This area was revisited in 2018 and no new sites were documented; data from survey efforts are currently under review.

In 2013 and 2014, SBS re-surveyed around the Collins Tract, but no Applegate's milk-vetch plants were observed within 100 feet of the Pipeline project (SBS 2013a and 2014). However, plants in a larger sub-population documented in 2008 (#15) approximately 100 feet southeast of MP 195.6 were observed within a fence. Also in 2014, surveyors noted that one smaller sub-population (#17) documented in 2008 south of MP 195.9 was at the site of a salt lick where the ground had been trampled to bare dirt and was likely extirpated (see figure 3.7.1-1).

In 2007, a portion of Klamath Falls Memorial Drive 2 / Bair proposed pipe storage yard was surveyed, where permitted; no Applegate's milkvetch plants or suitable habitat were observed (SBS 2008b). The area of the proposed pipe storage yard that plants were documented by FWS and TNC in 2009 (Klamath West survey site; ORBIC 2017c) had not been surveyed for the Pipeline project in 2008 due to a lack of landowner permission and a slightly different pipe yard configuration (see figure 3.7.1-2).

Critical Habitat

Critical habitat has not been designated for Applegate's milk-vetch.

3.7.1.3 Effects of the Proposed Action

The Pipeline project could affect federal threatened and endangered plant species (discussed here for Applegate's milk-vetch, and below for other plant species in their respective sections) through one or more of the following pathways:

1. Direct mortality of plants and/or destruction of seed banks during clearing and grading, construction, and reclamation.
2. Fragmentation and isolation of existing populations and areas of suitable habitat.
3. Damage or mortality of plants and/or seed banks due to increased off-road vehicle use in the Pipeline project area.
4. Increased populations of invasive noxious weed species that interfere with growth and survival of listed plants.
5. Damage or mortality of individual plants by dust deposited on photosynthetic surfaces during construction.
6. Changes in characteristics (shade, temperature, soil moisture, species composition, etc.) that alters suitable habitat.
7. Loss of pollinators due to habitat alteration, dust, and/or increased presence of invasive, noxious weeds.
8. Accidental release of toxic compounds during construction and/or operation.

Direct and Indirect Effects

The 1998 Recovery Plan identifies the small numbers and limited distribution as a threat to Applegate's milk-vetch because the possibility of extirpation due to random mortality events; therefore, any loss of plants could be considered significant because those plants could be a genetic link for subpopulations. The original 2007 Pipeline route coincided with five sub-populations within the Collins Tract site. In response to recommendations and discussions with state and federal agencies, PCGP rerouted the alignment north of its original 2007 route (FERC 2009) to lower elevations and wetter soils to avoid individual plants documented during surveys in 2008, as well as to avoid additional potential habitat (see figure 3.7.1-1 and figure A-1 in appendix V2). No direct effects to individual plants or suitable habitat in the Collins Tract population are expected. Surveys by FWS and TNC in 2009 identified approximately 175 plants within proposed Klamath Falls Memorial Drive 2 / Bair pipe storage yard. PCGP would survey for Applegate's milkvetch in the Klamath Falls Memorial Drive 2 / Bair pipe storage yard prior to avoid using portions of that pipe storage yard by at least 30 meters of documented and previously documented (i.e., ORBIC 2017c) Applegate's milk-vetch plants. Therefore, no direct impacts to individual plants at this pipe storage yard would be expected.

Although no known plants would be directly impacted by the Pipeline project in the Collins Tract site or within the proposed Klamath Falls Memorial Drive 2 / Bair pipe storage yard, surveys of all potential suitable habitats within the Pipeline project area have not been completed to date due to lack of access granted by landowners or more recent Pipeline alignments; therefore, it is possible that unidentified plants may occur within the proposed construction right-of-way or work areas. These plants could be in areas that would be directly impacted by the Pipeline project; however, PCGP has developed conservation measures aimed at avoiding or minimizing the risk of impacting unknown plants (see section 3.7.1.4, Conservation Measures and Applegate's milk-vetch mitigation plan, appendix V2).

Suitable habitats as well as plants within 30 meters of the Pipeline project may be indirectly impacted as a result of: 1) changes in hydrology and soil characteristics, 2) an increase in invasive weeds, and 3) alterations of vegetation cover and species composition. Impacts from fugitive dust created during construction and travel on unpaved access roads could also affect the photosynthetic surfaces of Applegate's milkvetch plants in the Pipeline vicinity; although dust abatement measures during construction would be employed according to PCGP's Air, Noise and Fugitive Dust Control Plan that would minimize the potential for this impact (see appendix B to the POD). These indirect impacts could negatively impact Applegate's milkvetch plants and habitat suitability since plants within the Collins Tract population are located within 30 meters (98 feet) of Pipeline project disturbance; the closest mapped sub-population (sub-population 17) is approximately 63 feet south of TEWA 195.74-W near MP 195.9 (see figure 3.7.1-1). However, to minimize potential impacts to critical life cycles, PCGP would construct the Pipeline between MPs 195.4 and 196.6 outside of the growing and reproductive season for this plant (after September 15 but before April 30). Construction of the Pipeline could also affect groundwater flow patterns located at the Collins Tract site, but since the Pipeline would be constructed outside of the irrigation season between MPs 195.4 and 196.6, shallow ground water perched on top of restrictive subsoil horizons is not expected to be present during construction. Travel along the existing paved access road (EAR 192.57-197.61) should not affect Applegate's plants within the Collins Tract population located adjacent to the access road. Indirect effects to plants within the Klamath Falls Memorial Drive 2 / Bair pipe storage yard should be minimized since PCGP would not utilize portions of the yard within 30 meters (98 feet) of documented plants. Indirect effects to unidentified Appelegate's milk-vetch and potentially suitable habitat could also occur in the vicinity of the Pipeline project that has not been surveyed to-date.

After construction, PCGP would restore the construction right-of-way back to approximate original contours to ensure that drainage patterns are restored and would reseed the affected area using a species mix recommended by FWS that is appropriate for the area. Impacts to Applegate's milk-vetch related to operation of the Pipeline would result from the monitoring and treatment of noxious weeds, which could affect non-targeted species (such as Applegate's milk-vetch) if they are near treatment areas. No other maintenance impacts are expected within the range of Applegate's milk-vetch because the permanent easement would be maintained in an herbaceous/shrub state, which would provide conditions similar to Applegate's milk-vetch suitable habitat.

Cumulative Effects

Because the extent of this species on these non-federal lands is unknown, it is not known if there are reasonably foreseeable actions that might occur on non-federal lands within areas currently occupied by this species. As the FWS's authority generally does not extend to listed plants on private or state lands,[12] all federally listed plants located on these lands could be considered at

[12] The ESA does not protect plants outside federal land unless there is a federal nexus. Therefore, activities that occur on private or state lands that could affect listed plants but which do not have federal nexus are not required to consult with the FWS. Plants may not be removed from lands under federal jurisdiction, and activities with a federal nexus must consult with the FWS.

risk of adverse effects from activities that could negatively impact the species. Other reasonably foreseeable projects on non-federal lands that could adversely affect this species include residential, commercial, and industrial development, grazing, as well as expanding agricultural areas.

The Applicant has committed to mitigating for any Pipeline project-related impacts to Applegate's milk-vetch, regardless of land ownership.

Critical Habitat

Critical habitat has not been designated for Applegate's milk-vetch; therefore, critical habitat for this species would not be impacted by the proposed action.

3.7.1.4 Conservation Measures

PCGP has developed a mitigation plan for Applegate's milkvetch (see Attachment 2 within the *Federally-listed Plant Conservation Plan*, appendix v2) to address how avoidance, minimization, seed collection, restoration, and other conservation measures would be applied to protect Applegate's milkvetch. This mitigation plan describes how PCGP has avoided direct impacts to documented plants within the Collins Tract population between MPs 195.5 and 196.6 through route modifications (see Figure A-1, appendix V2), as well as how PCGP would avoid documented plants within the Klamath Falls Memorial Drive 2 / Bair pipe storage yard by at least 30 meters (98 feet). Additionally, the plan describes construction methods that would minimize impact to Applegate's milkvetch plants and suitable habitat. For example, in Collins Tract population between MPs 195.35 and 196.50, PCGP would install trench plugs on either side of wetland ditch crossings to maintain the original wetland hydrology, as specified in FERC's Wetland and Waterbody Construction and Mitigation Procedures (VI.C.1.). After construction, the trench would be backfilled with the native trench spoil material generally in the same order that the trench was excavated. After the Pipeline is sufficiently covered with backfill material, the backfill in the trench would be compacted by tamping with the backhoe bucket or roller in a manner to prevent damage to the Pipeline. Subsequent trench backfilling would occur in lifts and compacted by tamping or rolling in an effort to restore approximate original soil physical conditions (densities / permeability).

When access to the construction right-of-way is granted, surveys for Applegate's milk-vetch would be conducted in potential habitat (previously surveyed or unsurveyed) and additional plants located during surveys would be avoided, if feasible. FWS would be notified of survey results and, if the species is present, the avoidance/conservation measures described in the Applegate's milkvetch mitigation plan (see appendix V2) would be implemented. The following lists some of the measures in the plan that would minimize or avoid effects to Applegate's milkvetch plants and habitat:

- Surveying and flagging the construction right-of-way and TEWAs to clearly mark the limits of construction disturbance (i.e., clearing/grading).
- To avoid listed plant species located within the Pipeline project, the construction right-of-way may be narrowed or necked down in some areas (i.e., in areas adjacent to listed plant species), and some TEWAs or UCSAs may be eliminated or a portion of the area removed from Pipeline use when feasible.

- Where feasible, the EI would monitor the survey and flagging efforts and would provide additional protective buffers or neckdowns to ensure protection of adjacent plant populations or provide additional avoidance. The EI would consult with PCGP's Chief Inspector and the construction contractor during construction to determine where additional buffer protections or neckdowns could be accommodated without affecting construction safety.
- Plant populations would be protected by safety fence and silt fence to ensure these plants are not inadvertently impacted by Pipeline activities.
- Topsoil would be segregated from trench spoil to maintain the soil seed bank, as well as maintain microrhyzoids with which the species' root system is associated. Topsoil salvaging would occur within the vicinity of affected populations after species-specific seed, bulb, or whole plant salvage has occurred. The salvaged topsoil would be returned to its original location during restoration.
- The construction right-of-way would be restored to its original contours and reseeded with an appropriate seed mixture recommended by FWS prior to the following growing season. PCGP would monitor revegetation success in the area reseeded between MPs 195.5 to 196.6, and other areas reseeded considering milk-vetch for five years after construction.
- PCGP would collect and bag seeds of any affected milkvetch plants prior to seed dispersal (June to July) and provide these seeds to a suggested repository. If permission is granted by the property owner, PCGP would use the collected seed to plant outside of the permanent right-of-way after construction (e.g., see replanting measures proposed for Applegate's milk-vetch).
- Wetland mats would be used in travel areas in saturated soil areas to minimize soil rutting and soil compaction and protect existing plants that may be present.
- To control the potential noxious weed invasion, the Applicant would implement the procedures outlined in their *Noxious Weed Control Plan* (see appendix N to the POD). Equipment would be inspected and cleaned of potential noxious weed seed or plant parts.

3.7.1.5 Determination of Effects

Species

The Project **may affect** Applegate's milk-vetch because:

- suitable habitat is present within the botanical analysis area; and
- individual plants have been located within the analysis area during survey efforts.

The Project is **likely to adversely affect** Applegate's milk-vetch because:

- potential suitable habitat occurs along the proposed route and comprehensive surveys have not been conducted in all areas; therefore, it is possible that unidentified plants occur within the proposed construction right-of-way and work area; and
- indirect impacts to Applegate's milkvetch plants and habitat are likely within 30 meters of the Pipeline project.

Critical Habitat

Critical habitat has not been designated for Applegate's milk-vetch.

3.7.2 Gentner's Fritillary

The Gentner's fritillary (*Fritillaria gentneri*) is a perennial in the lily family *(*Liliaceae). The plant grows on the edge of woodlands, with an overstory of Oregon white oak (*Quercus garryana*) and Pacific madrone (*Arbutus menziessii*), and also occurs in open chapparal and grassland environments, at elevations between 300 to 1,230 meters (approximately 1,000 to 4,200 feet). It is found in small, scattered locations in the Rogue and Klamath River watersheds in Jackson and Josephine counties, Oregon, with one small population recently discovered in northern California (FWS 2003d and 2016e).

3.7.2.1 Species Account and Critical Habitat

Status

Gentner's fritillary was listed as endangered on December 10, 1999 (FWS 1999b). Although this lily may have originated as a result of hybridization, it is considered a valid species.

Threats

A key factor in the FWS 1999 listing of Gentner's fritillary was the present or threatened destruction, modification, or curtailment of its habitat and range. FWS identified residential and utility development and agricultural conversion as the causes for these destroyed locations in its relatively isolated population. At that time, 73 percent of the known plants were in a central core area within a 7-mile radius of the Jacksonville Cemetery. FWS noted that habitat loss due to ongoing or future development might occur at 42 percent of the occupied sites (19 plots—all within the central core area; FWS 1999b). Loss of habitat is still a major threat to Gentner's fritillary. In the species' recovery plan (FWS 2003d), FWS identified agricultural, urban and residential development, timber harvest, road and trail improvement, and recreation as ongoing threats to the very narrow geographic range and small population size of the plant. The areas most threatened are on private lands. Habitat conversion due to fire suppression continues to be a problem, as well as weed and non-native plant proliferation and herbicide use. Species persistence and recovery is hampered by the very structure of its remaining populations, which are scattered, isolated, and small in size and number. These small populations are at high risk of decline because they lack reserves to ward off stochastic loss, overutilization for commercial and recreational purposes, diseases, climatic shifts, herbivory, localized natural disturbances, and decrease in genetic diversity (FWS 1999b and 2003d).

Species Recovery

A species recovery plan was released by FWS in 2003 that created four recovery units to delineate areas that are necessary for the viability and recovery of Gentner's fritillary. The objective of the recovery plan is to remove threats to the extent that Gentner's fritillary is no longer in danger of extinction and can be downlisted or delisted. The recommended recovery actions are listed below (FWS 2003d):

- Provide private landowners with information on identification and management of habitat.

- Establish a minimum of eight *Fritillaria* management areas, with at least two distributed within each of four recovery units.
- Conduct surveys and research essential to conservation and recovery.
- Develop off-site germplasm banks to maintain reproductive materials.
- Review and revise recovery plan as needed, based on accumulation of new data.

The recovery strategies for the recovery units include rehabilitation of habitat, restoration of historical sites, and augmentation of existing populations including expansion into nearby suitable habitat (FWS 2003d). Recovery units are considered individually necessary to the long-term viability of the species. The objective within each established recovery unit is to have at least 750 flowering plants to downgrade its status to threatened or 1,000 plants to delist the species, monitored biannually for at least 15 years. This recovery unit total may consist of many management areas within each recovery unit, including management areas as small as five flowering plants. Maintaining the subpopulations or population clusters within each recovery unit is important to preserve the genetic diversity within the species, ensure its long-term viability, and reduce the vulnerability of the species to extirpation from random catastrophic events (FWS 2003d).

Based on a 2013 monitoring report, only one of the four mapped recovery units (Unit 4) has attained over 1,000 flowering plants in the last two years; the other three recovery units have been below 750 flowering plants in the past 10 years (FWS 2016e), including Recovery Unit 3 that is located in northeastern Jackson County and is crossed by the Pipeline (MPs 117.7 to 142.2). Thirteen *Fritillaria* Management Areas (FMAs) have been established, which is one of the recommended actions identified to assist recovery of the species. Each recovery unit contains at least two FMAs and one of the FMAs occurs outside of the recovery units (FWS and BLM 2015 in FWS 2016e). Recovery unit boundaries will be revised and additional FMAs will be established to meet the recovery plan criteria (FWS 2016e). The Indian Creek FMA is the closest to the Pipeline and is approximately 1 mile southwest of MP 128.

Life History, Habitat Requirements, and Distribution

Gentner's fritillary is often found in grassland habitats within, or on the edge of dry, mixed forest types where overstory can be dominated by Oregon white oak, madrone, Douglas-fir, and ponderosa pine. It occurs at a wide range of elevations, from 1,000 to 4,200 feet, in the rural foothills of the Rogue River Valley of Josephine and Jackson Counties (FWS 2003d and 2016e; SBS 2008c). It is usually associated with shrubs that provide protection from the wind and sun.

The perennial reproduces clonally by means of numerous small bulblets that break off larger bulbs and form new plants. Sexual reproduction appears to be a sporadic or episodic event for the species, although observations suggest hummingbirds and some species of bees may pollinate the plant. Blooming season usually lasts from April through May, and plants must reach a minimum size before flowering (FWS 2003d).

The distribution of Gentner's fritillary is characterized by distinct clusters. The species is highly localized, with the populations occurring within a 30-mile radius of Jacksonville, Oregon, with approximately 45 percent of the plants occurring within an 11-mile radius (FWS 2003d). Since the 2003 publication of the recovery plan, nine new Gentner's fritillary populations (approximately 131 flowering plants within 1.6 acres) have been detected outside of the four recovery unit boundaries (FWS 2016e).

Population Status

It is often difficult to census populations of Gentner's fritillary because individuals can remain dormant for one or more years underground and not flower. Also, flowering plants can be grazed by deer or cattle before identification and counting can be performed and sometimes it cannot be distinguished from other non-flowering and co-occurring *Fritilleria* species, such as scarlet fritillary or chocolate lily (FWS 2003d). In 2001, Gentner's fritillary was estimated at 1,696 flowering individuals in Jackson and Josephine counties, and just south of the border in California (FWS 2003d). For over 10 years, BLM has monitored Gentner's fritillary flowers and leaves on 58 sites across all four recovery units and has observed that flowering plants at most sites fluctuate annually. The results indicate that flowering plant total has been generally increasing over the past seven years, with the exception of 2001 and 2014 (FWS 2016e). In 2013, it was estimated that approximately 2,907 plants occurred within the four recovery units, as well as outside the recovery units (Table 1 in FWS 2016e). Most Gentner's fritillary sites include a small number of individual plants, ranging from one to 450 individual plants (mean of 16 plants). The largest number of plants occurs on BLM lands, with 1,653 counted in 2005 during annual monitoring of 56 known sites (SBS 2008c). Inventories on other monitored sites counted 940 plants on private lands in Jacksonville and 424 at Pickett Creek (SBS 2008c).

Critical Habitat

Critical habitat has not been designated for Gentner's fritillary.

3.7.2.2 Environmental Baseline

Analysis Area

The botanical analysis area extends to 30 meters (98 feet) each side of the Pipeline project (construction right-of-way, TEWAs, UCSAs, rock source and disposal sites, and proposed storage yards) on lands that have potential habitat for listed plant species. This area generally corresponds to the extent of the area surveyed for sensitive and listed plant species during surveys conducted between 2007 and 2017, and correlates to a distance that indirect effects to plants could occur. Habitats that were focused on during the survey for this species included grassland habitats near the edge of forests (at least 100 feet from habitat removal on federal lands and at least 50 feet from habitat removal on non-federal, private lands).

Species Presence

The analysis area crosses the species' range from approximately MPs 113 through 155. Between 1948 and 2015, approximately 68 sites of Gentner's fritillary have been reported within 25 miles southwest and 6 miles northwest of the Pipeline between MPs 117 and 143, of which many locations are likely extirpated based on habitat conditions (i.e., canopy encroachment) and development (ORBIC 2017c). The proposed Pipeline would cross Gentner's fritillary Recovery Unit 3, which is one of four clusters of fritillary sites proposed for conservation management within the 2003 recovery plan. One of the most vigorous plant populations in Recovery Unit 3 is approximately 1.2 miles southeast of MP 134.4 in the Obenchain Mountain area within the BLM Medford District (Friedman 2006; ORBIC 2017b; SBS 2008a). In 2005, observations at the site reported 19 plants but just one plant in 2009 with the population rated as poor viability (ORBIC

2017c). Pipe storage yards in Jackson County are located more than three miles away from several documented populations in Sam's Valley (Friedman 2006). None of the previously known sites mentioned above are located within the botanical analysis area but they are still within the recovery unit; the closest plant provided by ORBIC (2017c), outside of plants documented for the Pipeline (see below), was documented by Medford BLM in 2010, approximately 500 feet northeast of MP 127.5. Botanical surveys by PCGP between 2007 and 2018 located five sites that contain Gentner's fritillary, as described below.

Project-Specific Surveys

Habitat Surveyed. Prior to beginning field surveys in 2007 for the Pipeline project, botanists with SBS conducted a habitat review to identify potential habitat and delineate survey areas for Gentner's fritillary within the botanical analysis area, including potentially suitable habitats adjacent to existing roads identified for access to the construction right-of-way. Aerial photographs and knowledge of regional landscape and biological features (soils, geology, topography, elevation, target species habitat, and associated plant community habitat) were used to determine the location of potential habitat for Gentner's fritillary. These same methods were applied to determine areas of suitable habitat in new locations where the proposed right-of-way has been relocated since 2007.

Recommended two-year surveys were conducted for this species where survey permission was granted within the vicinity of the Pipeline project (within at least 50 or 100 feet of the Pipeline project on non-federal and federal lands, respectively and where permitted) and along proposed access roads (within at least 50 feet of access roads where road improvements are proposed and surveys permitted). Most surveys were conducted in 2007 and 2008, but additional two-year surveys have been conducted since 2008 in areas of reroutes, minor route adjustments, and areas where survey permission was subsequently granted. Additionally, PCGP initiated two-year survey protocols in 2017 within previously surveyed suitable habitat where Pipeline project survey efforts are or will be 10 years old prior to the completion of the Pipeline, per direction included in the 2016 5-year review (FWS 2016e). Surveys have continued in 2018 and the data are currently under review.

Overall, approximately 2,130.91 acres have been surveyed by PCGP from 2007 through 2017 for Gentner's fritillary within the vicinity of the proposed Pipeline, including previously proposed routes and project components, alternate routes considered, and along access roads that are no longer considered for the Pipeline project. Within the 30-meter botanical analysis area of the Pipeline, approximately 1,720 acres between MPs 113 and 155 have been identified as potential suitable habitat requiring surveys (see table 3.7.2-1). Of this habitat, access was granted to about 1,467 acres (588 acres within the Pipeline project), including within 50 feet of access roads where road improvements have been proposed. Some of the areas surveyed on private lands or areas surveyed on federal lands within recent reroutes only received one year of surveys; habitat on federal lands were surveyed again in 2018.

TABLE 3.7.2-1

Summary of Potential Suitable and Survey Status for Gentner's Fritillary Habitat within the Botanical Analysis Area

General	Suitable	Total Acres	Acres Surveyed (RESURVEYED [4])	Acres Not Surveyed [5]

Landowner	Habitat Status	Surveyed [1] (2007-2017)	Project [2]	Buffer [3]	Total	Project [2]	Buffer [3]	Total
MPs 113.0 - 155.0 (1,720.45 acres within botanical analysis area)

[1] Acres provided in this column considers all surveys to-date (through 2017), including areas that have been subsequently rerouted or dropped (i.e., pipe yards) since surveys were initiated in 2007.
[2] Project includes: right-of-way, temporary extra work area, uncleared storage area, rock storage, pipe yards, aboveground facilities.
[3] Buffer (botanical analysis area) includes area within 30 meters (98 feet) of habitat removal and within 50 feet either side of an existing access road identified with possible road improvements.
[4] Per FWS request (May 2017), PCGP has reinitiated surveys in suitable habitat where survey effort was or would be 10 years old (acres surveyed). Survey efforts began in 2017 and would continue in 2018 and/or 2019 where access is permitted.
[5] Areas not surveyed are either denied access or were not surveyed because of recent modification in Proposed Route that occurred after the flowering season, as well as areas outside of the targeted survey area (i.e., 30-meter analysis area vs. 50-foot targeted survey area on non-federal lands). "Not Habitat" was determined from adjacent survey parcel information, aerial photography, or "drive-by;" no surveys would be necessary and acres are not included.

Note: Surveys have continued in 2018 and the data are currently under review. Most area that remains to be surveyed occurs on private lands; surveys would continue as access becomes available.

Of the 1,467 acres of potential habitat within the botanical analysis area with survey access, 1,227 acres (487 acres within the Pipeline project construction right-of-way) were considered suitable habitat for Gentner's fritillary. Habitat suitability was assessed based on standards from a state-wide Gentner's fritillary habitat analysis protocol (SBS 2001). Habitat found to be "suitable" supported characteristics as detailed in the previous sections (SBS 2008a).

Approximately 241 acres (50 acres within the Pipeline project footprint) of potentially suitable habitat (or unknown habitat status) for this species within the botanical analysis area was denied access by the landowner, or occurs within recent modifications of the Pipeline project. Most of this unsurveyed habitat occurs on non-federal (private) lands, Habitat unsurveyed on federal lands includes an area within a recently proposed reroute and surveys would be initiated in 2018. Since permission to survey on non-federal lands targeted an area of at least 50 feet from the Pipeline project, it is very likely that habitat within the "buffer" (30-meter botanical analysis) area would not be surveyed. PCGP would continue to survey habitat following the 2-year survey protocol where permission is granted. Where survey access has been denied, PCGP would conduct one year of surveys in suitable habitat prior to construction. Until survey data is obtained, for purposes of analysis, a conservative assumption can be made that a similar percent of the unsurveyed area would contain suitable habitat (compared to the areas where surveys have been completed), which means approximately 201 acres within the botanical analysis area (83.6 percent of 241 acres, or 42 acres within the Pipeline right-of-way) could be suitable fritillary habitat.

Survey Results. Surveys for Gentner's fritillary have occurred within suitable habitat in the vicinity of the Pipeline from 2007 through 2018. Surveys are expected to continue to complete second year survey efforts where necessary, as well as initiate surveys in other areas that receive survey permission. Since 2007, Pipeline-specific surveys have identified five sites with Gentner's fritillary, of which three sites have been located in the botanical analysis area (SBS 2008a; SBS 2011; SBS 2013b):

- In 2011, two sites containing three flowering plants and nine *Fritilleria* spp. leaves were located 40 feet apart approximately 21 feet southeast of TEWA 128.01-W near MP 128.1; subsequent surveys for an unrelated BLM Project identified approximately 150 *Fritillaria* spp. leaves (see figure 3.7.2-1).

- In 2013, two flowering plants were documented 70 feet apart near MP 129.1 approximately 54 feet northeast of TEWA 128.96-N, with at least 500 bulb leaves in approximately 0.30 acre, of which some could be Gentner's fritillary (one flowering plant observed again in 2015; ORBIC 2017c; SBS 2015) (see figure 3.7.2-2). This site was observed approximately 1 mile east of the site documented in 2011 near MP 128.1.

- In 2008, one flowering Gentner's fritillary plant (with no leaves) was located near MP 142.10 within 21 feet of proposed TEWA 142.07-N (PCGP modified TEWA 142.07-N to avoid the documented flowering Gentner's fritillary plant). There were 18 additional fritillary species (*Fritillaria* sp.) with leaves located within 150 feet of the flowering site, as well as two other flowering fritillary species (scarlet fritillary [*F. recurva*] and chocolate lily [*F. biflora*]). It is possible that some of the leaves located within this area could be Gentner's fritillary; therefore, a larger area which includes all un-identified *Fritillaria* sp. leaves documented is considered part of the potential *F. gentneri* population area (approximately 0.83 acre) that occurs within TEWA 142.07-N and the construction right-of-way (see figure 3.7.2-3).

- Two additional sites were documented during 2008 surveys along existing roads, including one flowering plant and two *Fritillaria* spp. leaves approximately 0.38 miles north of MP 128.05 near Indian Creek and 50 feet below a four-wheel drive road, and four flowering plants 1.0 mile southwest of MP 128.2 and 100 feet from the existing road, which was verified again in 2010 (ORBIC 2017a). These sites are located along roads that will no longer be used for the Pipeline project.

The five sites identified during survey efforts for the Pipeline are 0.4 to 11.2 miles from each other and therefore are not considered a "population center" by the recovery plan definition (four or more locations must occur within 0.3 mile of each other; FWS 2003d). However, BLM and Forest Service have indicated that additional populations have been observed in the Pipeline vicinity during survey efforts for unrelated projects, and, in conjunction with the sites located for the Pipeline project, would be considered a population center.[13]

Critical Habitat

Critical habitat has not been designated for Gentner's fritillary.

3.7.2.3 Effects of the Proposed Action

Direct and Indirect Effects

Five new Gentner's fritillary locations (supporting 11 flowering plants and 679 *Fritillaria* spp. leaves total) were identified during surveys conducted for the Pipeline project, of which three sites (six flowering plants, and 677 *Fritillaria* spp. leaves) occur within the botanical analysis area (see figures 3.7.2-1, 3.7.2-2, and 3.7.2-3). As this species has very low overall population numbers, any loss of individual plants could be considered a substantial impact to the species.

No direct effects are expected at the two sites located within the 30-meter botanical analysis area but are 21 to 54 feet from the Pipeline near MP 128.1 and MP 129.1, respectively (see figures 3.7.2-1 and 3.7.2-2). At the other site near MP 142.1, PCGP removed a portion of TEWA 142.07-N to avoid direct impact to the one flowering Gentner's fritillary plant documented at this site, following recommendations of the Habitat Quality Subtask Group on July 24, 2008; however, several unidentified *Fritillaria* sp. leaves that could be a part of a potential Gentner's fritillary sub-population would be directly affected by construction of the Pipeline (see figure 3.7.2-3 and figure G-3 in appendix V2). Because the site near MP 142.1 consists of a single plant or perhaps a small cluster of plants, it is more vulnerable to extirpation due to even small-scale losses of habitat or plants (FWS 2003d). PCGP has determined that a minor route adjustment of the proposed alignment could be implemented to completely avoid direct effects to the potential Gentner's fritillary sub-population, including the unidentified *Fritilleria* sp. leaves; however, PCGP would need to consult with the landowner to determine if the landowner is agreeable to the revised route. PCGP would conduct additional surveys of this area prior to construction to verify species and/or locate the extent of the potential sub-population and/or additional *Fritilleria* spp. leaves and incorporate additional survey information within a route adjustment prior to construction.

[13] The fritillary sites in section 25 are considered a "population center" because there are four known locations within 0.3 mile of each other, with another three locations within 0.4 mile of the group of four. This cluster of populations is located in the center of Recovery Unit 3, which consists of intersecting circles around a cluster of populations in the Antioch Road area and a cluster of populations in the Cobleigh Road area. The "Indian Creek" cluster and additional sites within 1.5 miles in Section 19, T.34S., R.1E and Section 29, T.34S., R.1E, create a third cluster of populations within RU3. Although fritillary management areas have not been identified in this area, it is assumed that the Indian Creek cluster would be considered for designation as a management area. Hence, the BLM has an interest in protecting and augmenting these populations. Most of these populations were discovered by the BLM during botany clearance surveys conducted in preparation for renewing a grazing allotment permit (not connected with this Pipeline project).

Because Gentner's fritillary does not flower every year and remains dormant underground for one or more years, it is likely that not all plants within areas surveyed for the Pipeline project were documented during the two-year survey effort. Therefore, it is possible that construction activity within identified suitable habitat could directly impact individual plants. Although no direct impacts are expected to occur to identified plants (see discussion above), direct impacts could occur to currently unidentified plants within unsurveyed habitat. However, PCGP intends to conduct additional surveys prior to construction and if plants are documented, direct impacts will be avoided or minimized, where possible following measures outlined in the Gentner's Fritillary Mitigation Plan (see Attachment 3 within the *Federally-listed Plant Conservation Plan*, appendix V2).

Approximately 240.86 acres (table 3.7.2-1) of suitable and potentially suitable habitat (unsurveyed areas) between MPs 113 and 155 would be disturbed by construction of the Pipeline. The construction process could result in indirect impacts to Gentner's fritillary plants and habitat within 30 meters of the Pipeline project, which would include: 1) changes in hydrology and soil characteristics; 2) a potential increase in invasive weeds, which could create additional competition for Gentner's fritillary plants; 3) increased fugitive dust, which could clog stomatal openings in leaves and impede gas exchange, as well as reduce light availability at the leaf surface that could affect plant growth and seed production; and 4) alterations of vegetation cover and species composition, which could impact shading and other interspecific interactions that could negatively impact this species or its ability to re-colonize disturbed areas.

However, the impacted habitat in the analysis area represents a very small percentage of total suitable habitat in the species' range (SBS 2008c); therefore, direct or indirect disturbance to habitats within or adjacent to the Pipeline project is not expected to impede recovery of the species. To control the potential noxious weed invasion, PCGP would implement the procedures outlined in their *Noxious Weed Control Plan* (see appendix N to PCGP's POD). Application of dust abatement measures included in PCGP's Air, Noise and Fugitive Dust Control Plan (see appendix B to PCGP's POD) would minimize the potential for impacts to Gentner's fritillary plants and its habitat during Pipeline construction.

Operation and maintenance of the Pipeline would occur within suitable Gentner's fritillary habitat. Vegetation within the 30-foot operational corridor would be periodically maintained using mowing, cutting, trimming, and herbicides (selectively). Maintenance activities are expected to occur approximately every 3 to 5 years depending on growth rate. However, these activities should not have an adverse effect on Gentner's fritillary because maintenance activities, if necessary, would occur outside the critical growing and flowering season (April through May). If noxious weed infestation occurs within the 50-foot permanent easement, selective use of herbicides or mechanical treatments would be used to control weed within proximity to the species. The Applicant's protection procedures are outlined in the *Noxious Weed Control Plan* (see appendix N to PCGP's POD).

Cumulative Effects

Outside of the areas surveyed for this Proposed Action, it is unknown where Gentner's fritillary occurs on lands not under federal jurisdiction. Therefore, because the extent of this species on non-federal lands is unknown, it is uncertain if there are reasonably foreseeable actions that might occur on these lands within areas currently occupied by this species. As the FWS' authority generally does not extend to listed plants on private or state lands,[14] all federally listed plants located on these lands must be considered at risk of adverse effects from potential developments. Other reasonably foreseeable projects on non-federal lands that could adversely affect this species include residential, commercial, and industrial development, as well as expanding agricultural areas.

PCGP has committed to implementing mitigation measures on private lands.

Critical Habitat

Critical habitat has not been designated for Gentner's fritillary; therefore, no designated critical habitat for this species would be impacted.

3.7.2.4 Conservation Measures

As described for the Applegate's milk-vetch, PCGP has developed a *Federally-listed Plant Conservation Plan* to address how avoidance, minimization, propagation, restoration, and other conservation measures would be applied to protect listed plant species, as well as how potential impacts on un-surveyed lands would be addressed. This plan also contains a Gentner's Fritillary Mitigation Plan that specifically addresses how avoidance and minimization meausres would be implemented for the Gentner's fritillary (see Attachment 3 within the *Federally-listed Plant Conservation Plan*, appendix V2).

To avoid all direct impacts to known Gentner's fritillary flowering plant(s) documented in the Pipeline project, PCGP has modified TEWA 142.07-N (see figure 3.7.2-3 and figure G-3 in appendix V2); all other known Gentner's fritillary plant locations are located outside of the Pipeline project. Additionally, PCGP has identified a reroute that would avoid the unidentified *Fritillaria* sp. leaves located within TEWA 142.07 and the construction right-of-way; however, PCGP would need to consult with the landowner to determine if the landowner is agreeable to the revised route. PCGP would conduct additional surveys near MP 142.1 to verify the presence or absence of *Fritilleria* spp., as well as identify any additional flowering plants or *Fritilleria* spp. leaves that should be considered within the proposed route adjustment prior to construction.

When access to the construction right-of-way is granted, surveys would be conducted in potential habitat (previously surveyed or unsurveyed). Where survey access has been denied, PCGP would conduct at least one year of surveys in suitable habitat prior to construction and would conduct a second year of surveys if possible. Also, PCGP would continue to resurvey areas of suitable habitat where previous Pipeline survey efforts are or will be 10 years old prior to the construction of the Pipeline. FWS would be notified if additional plants are documented. If plants are present, the avoidance/conservation measures included in the Gentner's fritillary mitigation plan would implemented, where feasible (appendix V2). Measures of avoidance may include necking down the construction right-of-way in that area, excluding a portion of an identified TEWA or pipe storage yard, or erecting a protective fence to avoid impact to plants

[14] The ESA does not protect plants outside federal land unless there is a federal nexus. Therefore, activities that occur on private or state lands that could affect listed plants but which do not have federal nexus are not required to consult with the FWS. Plants may not be removed from lands under federal jurisdiction, and activities with a federal nexus must consult with the FWS.

from construction debris. If it is determined that avoidance is not possible, propagation of collected bulblets followed by offsite cultivation for population augmentation could be a viable conservation measure (SBS 2008a). This procedure might include:

- identification and tagging plants for propagation during spring flowering (April in lower elevation, May in higher elevations);
- collection of bulblets during dormant season (late summer to fall-August through November);
- cultivation of bulblets off-site; or
- replanting of grown-out bulbs in subsequent years' dormant season.

Additionally, similar avoidance and conservation measures described above in section 3.7.1.4 for Applegate's milkvetch would be implemented, as described in the Gentner's fritillary mitigation plan (appendix V2), to avoid or minimize effects to Gentner's fritillary plants and habitat.

3.7.2.5 Determination of Effects

Species

The Project may affect Gentner's fritillary because:

- suitable habitat occurs within the botanical analysis area, and
- individual plants have been located within the analysis area during survey efforts.

The Project is **likely to adversely affect** Gentner's fritillary because:

- not all potential suitable habitat within the botanical analysis area was surveyed due to landowner access denial;
- Gentner's fritillary can remain dormant underground for 1 year or longer, does not flower every year, and has been documented to not flower for several years; therefore, it is possible that protocol surveys conducted for the Pipeline did not locate this species; and
- *Fritillaria* spp. leaves were documented within and adjacent to the Pipeline project, and, without flowers, it is nearly impossible to determine if those leaves belong to Gentner's fritillary or another *Fritillaria* species.

Critical Habitat

Critical habitat has not been designated for Gentner's fritillary.

3.7.3 Large-Flowered Woolly Meadowfoam

The large-flowered woolly meadowfoam (*Limnanthes pumila* ssp. *grandiflora*) is an annual plant species in the meadowfoam family (Limanthaceae). It is restricted to the wetter, inner fringes of vernal pools at elevations between 1,220 and 1,540 feet. The plant is found in the Agate Desert in the Rogue River Valley of Jackson County, Oregon (FWS 2002b and 2010c).

3.7.3.1 Species Account and Critical Habitat

Status

The large-flowered woolly meadowfoam was listed as endangered on November 7, 2002 (FWS 2002b). In 2010, FWS (2010c) designated 8 critical habitat units (5,840 acres) for this species in Jackson County, Oregon in the Agate Desert complex.

Threats

A major factor in the FWS 2002 listing of the large-flowered woolly meadowfoam was the present or threatened destruction, modification, or curtailment of its habitat (vernal pools) and range (FWS 2002b). Due to recent rapid population increases in the region, the primary threats to the plant's habitat and range in the Agate Desert (Jackson County, Oregon) are industrial, commercial, and residential development and their residual road and utility construction and maintenance that include mowing, herbicide use, firebreak construction, and hydrologic alteration (mostly for agriculture) (FWS 2011g).

Grazing can have a mixed effect on large-flowered woolly meadowfoam. The effect of grazing on suitable habitat depends on how the grazing is managed. There are various reports showing how grazing practices can positively or negatively affect native plant species' richness (Marty 2005). The Marty (2005) study indicates that wet season grazing resulted in a decrease of native forb species at vernal pool edge habitat, but year-round or off-season grazing improved species' richness through reducing competition with rough/weedy species.

Although disease (e.g., fungal infections), herbivory, and the meadowfoam fly (*Scaptomyza apicalis)* have been identified as potential problems, no data other than casual observations exist to suggest that these factors currently pose a substantial threat to the species (FWS 2012h).

Species Recovery

In November 2012, the FWS (2012h) finalized the *Recovery Plan for Rogue and Illinois Valley Vernal Pool and Wet Meadow Ecosystems* that identifies nine core areas for protection of vernal pool species in the Rogue Valley that are federally listed or have federal species of concern designation, including the large-flowered woolly meadowfoam. Four Priority 1 core areas are area identified by the FWS that are essential to prevent extinction or irreversible decline of this species, and five Priority 2 core areas are areas identified that are necessary to prevent a significant decline in the species population or habitat quality or some other significant negative impact. The recovery objectives specific to the large-flowered woolly meadowfoam include:

- stabilize and protect populations of the listed species in core areas so further decline in species' status and range are prevented;
- minimize or eliminate the threats that caused the species to be listed, and any other newly identified threats, in order to be able to delist the species;
- conduct research necessary to refine downlisting and recovery criteria;
- ensure long-term conservation; and
- promote natural ecosystem processes and functions by protecting and conserving, in identified core areas, intact vernal pool-mounded prairie complexes and seasonally wet serpentine-derived grassland meadows, sloped mixed-conifer forest openings, and shrub dominated plant communities.

Delisting criteria specific to large-flowered woolly meadowfoam include:

- At least 16 of 18 occurrences for large-flowered woolly meadowfoam (approximately 90 percent of documented/extant occurrences) should be protected from development.
- At least 90 percent of suitable vernal pool habitat acreage within the four Rogue Valley Priority 1 core areas for the species and at least 85 percent of suitable vernal pool habitat acreage within the five Priority 2 core areas for the species has been protected from development. All suitable habitat must include soils and hydrology that support the plant species.
- Develop management plans for each protected core area to guide protection and conservation , including vegetation control such as noxious weed control, monitoring, and maintaining hydrological function.
- Additional species occurrences identified through future site assessments, GIS, other analyses, or status surveys, and that are determined essential to recovery, are protected.
- Seeds from each core area should be collected and stored as insurance against the risk of extirpations and to ensure that genetic lines are preserved. Seed banking is also necessary to complete the reintroductions or introductions that can contribute to meeting recovery criteria.

Life History, Habitat Requirements, and Distribution

The large-flowered woolly meadowfoam is an annual herb endemic to the Agate Desert area in southern Oregon. It grows on the wetter, inner edges of vernal pools mostly in the Rogue River Valley, and is not known from wet meadows. Vernal pool-mounded prairie habitats sustain wet soils needed for growth and flowering, and the shallow pools provide for nutlet dispersal for this species' relatively short life cycle (FWS 2006f). The plant is capable of self-fertilization and self-pollination. Flowering occurs between March and May, with flowers producing nutlets. These nutlets may be dispersed by water, but normally only for short distances; therefore, it is likely that they do not disperse beyond their pool or swale of origin without transportation of mud or substrates containing nutlets (such as on the legs or feet of water birds, or on animal fur).

Large-flowered woolly meadowfoam occupies a limited portion of the Rogue Valley. The plant typically occurs in areas mapped with Agate-Winlo soils (FWS 2012h). There are no major ecological, genetic, or geographic barriers separating extant and historical large-flowered woolly meadowfoam occurrences, apart from agricultural and rural development and road systems. All known populations comprise approximately 177 hectares (440 acres), and are grouped into nine core areas that are separated by at least 1 kilometer (0.7 mile). In the Rogue River Valley, large-flowered woolly meadowfoam is found in the same vernal pool habitats as Cook's lomatium and the vernal pool fairy shrimp.

Population Status

Since listing the large-flowered woolly meadowfoam in 2002, the number of known populations (or occurrences) has increased. At the time of listing in 2002, there were 15 known occurrences of large-flowered woolly meadowfoam. In 2006, a draft recovery plan for listed species of the Rouge Valley vernal pool ecosystem was developed that indicated 22 occurrences were known (FWS 2006f). The most recent five-year review of the species in 2011 noted that 23 occurrences are known (FWS 2011g). Portions of 12 occurrences occur on public lands, within conservation easements, or on lands managed by The Nature Conservancy (FWS 2009e), and thus are protected from development. The population of this species fluctuates annually depending on precipitation and temperature, and so fluctuating populations at the various sites of occurrence have a broad range of approximately 100 to 100,000 (FWS 2006f). In April of 2017, the FWS initiated a 5-Year Status Review (FWS 2017c).

Critical Habitat

Critical habitat was designated in 2010 and included eight critical habitat units in Jackson County totaling 2,363 hectares (5,840 acres; FWS 2010c). The PCEs for large-flowered woolly meadowfoam critical habitat include (FWS 2010c):

1. Vernal pools or ephemeral wetlands and the adjacent upland margins of these depressions that hold water for a sufficient length of time to sustain large-flowered woolly meadowfoam, growth, and reproduction, between elevations of 1,220 to 1,540 feet, a minimum of 20 acres, and associated with specific dominant native plants.
2. The hydrologically and ecologically functional system of interconnected pools, ephemeral wetlands, or depressions within a matrix of surrounding uplands that together form vernal pool complexes within the greater watershed.
3. Silt, loam, and clay soils that are of alluvial origin, with a 0 to 3 percent slope, primarily classified as Agate-Winlo complex soils, but also including Coker clay, Carney clay, Provig–Agate complex soils, and Winlo very gravelly loam soils.
4. No or negligible presence of competitive, nonnative, invasive plant species.

In the Rogue River Valley, large-flowered meadowfoam is found in the same vernal pool habitats as Cook's lomatium and the vernal pool fairy shrimp, and as a result, most of the critical habitat units designated for large-flowered woolly meadowfoam partially overlap designated habitat for Cook's lomatium and/or vernal pool fairy shrimp. For example, two units designated for the large-flowered woolly meadowfoam in Jackson County are shared by the designated critical habitat for Cook's lomatium (i.e., White City and Whetstone Creek, see below for more details).

3.7.3.2 Environmental Baseline

Analysis Area

For most listed plant species, the botanical analysis area extends to 30 meters (98 feet) each side of the Pipeline project (construction right-of-way, TEWAs, UCSAs, rock source and disposal sites, and proposed storage yards) on lands that have potential habitat for listed plant species. This area generally corresponds to the extent of the area surveyed for sensitive and listed plant species during surveys conducted between 2007 and 2017 (at least 100 feet from habitat removal on federal lands and at least 50 feet from habitat removal on non-federal, private lands), and correlates to a distance that indirect effects to plants would be expected. For the large-flowered woolly meadowfoam, the analysis area was extended 250 feet from the perimeter of four proposed pipe storage areas that are located within the Vernal Pool Complex – Agate Desert, Jackson County, Oregon and shown in figure 3.7.3-1, as well as along the Pipeline right-of-way where Agate-Winlo soil complex occurs. This is a distance within which indirect effects from the Proposed Action could occur to vernal pools supporting this species (FWS 2011h).

Species Presence

Within the vicinity of the Pipeline project, large-flowered woolly meadowfoam is known to occur within the Agate Desert and is associated with Agate-Winlo soils in Jackson County, Oregon. There are multiple records of large-flowered woolly meadowfoam within the Agate Desert southwest of the Pipeline right-of-way (ORBIC 2017c). The closest record to the Pipeline right-of-way is a population with poor viability, last observed in 1982 approximately 3.3 miles southwest of MP 125.3. Other, more distant populations occur 5.8 to 6.9 miles southwest of the Pipeline right-of-way, including, one population of about 400 observed in 1995, another population rated as good or excellent in 2000 with approximately 1,000 plants, and a population discovered in 2008 with about 500 plants scattered across 100 acres. ORBIC (2017c) has reported several other sub-populations of large-flowered woolly meadowfoam (16,200 plants) in the vicinity of proposed pipe storage yards (Burrill Lumber, WC Short, Ave F & 11th St, and Rogue Aggregates), including within the Ken Denman State Game Management Preserve across an existing paved road and east of the Burrill Lumber pipe storage yard (ORBIC 2017b).

Project-Specific Surveys

Habitat Surveyed. Four pipe storage yards have been proposed within the Agate Desert near White City in Jackson County in proximity to known occupied vernal pools and designated large-flowered woolly meadowfoam critical habitat: Burrill Lumber, WC Short, Ave F & 11th St, and Rogue Aggregates (see figure 3.7.3-1). With the exception of Rogue Aggregates, all pipe yards proposed occur on Agate-Winlo complex soils. Although the pipe storage yards are within existing industrial sites, protected vernal pools that may support the large-flowered woolly meadowfoam could be present. Where survey access was permitted, pipe storage yards were evaluated on-site to identify vernal pool habitat, and where vernal pools were observed, surveys for large-flowered woolly meadowfoam occurred (see table 3.6.1-1).

In 2007, SBS identified vernal pool habitat in and near possible pipe storage yards in Jackson County that could provide habitat for the large-flowered woolly meadowfoam, (Cook's lomatium and vernal pool fairy shrimp, discussed in sections 3.7.4 and 3.6.1, respectively). Surveys for the federally-listed plants occurred in the proposed Burrill Lumber pipe yard and Rogue Aggregates pipe yard in 2007; no vernal pools were identified in the two proposed pipe storage yards, although approximately 4.4 acres of high quality suitable vernal pool habitat was observed 850 to 1,165 feet east of Burrill Lumber pipe storage yard where large-flowered woolly meadowfoam was documented (see figure 3.7.3-1 for large-flowered woolly meadowfoam; SBS 2008b). In 2018, habitat north of Burrill Lumber was assessed off-site to determine if possible vernal pools were present within 250 feet of the yard; based on observations from Agate Road and review of aerial photography, no potential vernal pools are located within 250 feet of Burrill Lumber pipe yard. Although Rogue Aggregates pipe yard has been reconfigured since surveys in 2007, portions not included in previous survey efforts for the Pipeline project are not expected to provide suitable habitat for large-flowered woolly meadowfoam because they do not contain suitable soil types.

No surveys have been permitted within Avenue F & 11th Street and WC Short pipe storage yards. Based on aerial photography and off-site observation in April 2018, Avenue F and 11th and WC Short pipe yard do not appear to contain vernal pools: Avenue F and 11th pipe yard is highly disturbed and graded, with railroad and docking faciltities located on the southern edge of the yard, and WC short pipe yard is an existing train yard that would assist moving and off-loading pipe. Although no vernal pools have been observed in Avenue F and 11th pipe yard, there is a long drainage ditch that runs along the northern edge of the pipe yard and paved Avenue F road and extends south along the western edge of the yard; the drainage has very little movement and could be considered low quality vernal pool habitat (approximately 0.46 acre), but because of the existing disturbance at this pipe yard, this habitat is not expected to support large-flowered woolly meadowfoam. No potential vernal pools have been identified in WC Short, and two small exposed drainage ditches (0.02 acre), in an otherwise underground piped drainage system, experience occasional high flow. They are located along an existing access road (Avenue G) within WC Short pipe yard and would not be considered potential vernal pool habitat.

In 2007, a much larger area previously considered for the Burrill Lumber pipe storage yard was also evaluated. High quality suitable vernal pool habitat (approximately 4.4 acres) was observed 850 to 1,165 feet east of the currently proposed Burrill Lumber storage yard where 36 large-flowered woolly meadowfoam were observed (SBS 2008a). Additionally in 2007, two other pipe yards that are no longer included for the proposed Pipeline project were evaluated (11 acres of suitable vernal pool habitat were observed and surveyed south of Ave F & 11th Street pipe yard within Avenue C and 7th Street pipe yard [10.5 acres in seven seasonally saturated pools] and north of Ave F & 11th Street pipe yard within Medford Industrial Park pipe yard [0.55 acre in 20 seasonally saturated pools; see figure 3.7.3-1]). Although suitable vernal pool habitat was present, no plants were observed during species-specific survey efforts (SBS 2008a).

Although out of the expected range of large-flowered woolly meadowfoam, nine vernal pools located in Agate-Winlo soils (approximately 0.2 acre) within and adjacent to the Pipeline project on private lands (MPs 145.3 to 145.40) were surveyed in 2007; no large-flowered woolly meadowfoam were documented (SBS 2008a).

Approximately 190.29 acres within 250 feet of proposed pipe storage yards, including Avenue F & 11th Street and WC Short pipe yards, in Jackson County have not been evaluated on-site for vernal pool habitat; off-site observations identified approximately 0.48 acre of highly modified, low quality vernal pool habitat within 250 feet of proposed pipe. Although 0.48 acre of potential vernal pool habitat has not been surveyed on-site for large-flowered woolly meadowfoam, the area is associated with active industrial sites or previously disturbed industrial areas and is not expected to provide high quality vernal pool habitat for the large-flowered woolly meadowfoam (table 3.6.1-1).

<u>Survey Results</u>. Within the high quality vernal pool habitat east of proposed Burrill Lumber pipe yard, four small patches (36 plants) of large-flowered woolly meadowfoam were found more than 1,530 feet east of the currently proposed pipe storage yard. The site is located on a portion of the property that has not been heavily modified (SBS 2008a; see figure 3.7.3-1). The plants located are suspected to be part of a larger large-flowered woolly meadowfoam population located to the east within critical habitat subunit RV6D. No other large-flowered woolly meadowfoam plants were observed during surveys within vernal pool habitat for the Pipeline project.

Critical Habitat

Within the vicinity of White City, Oregon where four pipe storage yards are proposed, critical habitat units RV6 (6A through 6H) and RV8 have been designated; all units are surrounded by industrial parks and agriculture. Both critical habitat units consist of intact vernal pool-mounded prairie and swale habitats (FWS 2010c). Two of the eight RV6 subunits (i.e., RV6C and RV6D) are near or adjacent to proposed yards: unit RV6C is across an existing paved road from Burrill Lumber pipe storage yard and unit RV6D is 590 feet northeast of Burrill Lumber pipe storage yard. RV8 is over 1.8 miles west of the proposed Rogue Aggregates and the other three pipe storage yards (see figure 3.7.3-1).

3.7.3.3 Effects of the Proposed Action

Direct and Indirect Effects

Possible direct effects to large-flowered woolly meadowfoam include disturbance to pools from driving on or storing equipment or pipes near or on pools or wetlands associated with this species. Direct effects to the meadowfoam and its habitat could be expected in vernal pools and upland habitat within 100 feet from delineated vernal pool habitat. Because no vernal pool habitat has been documented in surveyed Jackson County proposed pipe storage yards (Burrill Lumber and Rogue Aggregates), and because PCGP has committed to avoiding vernal pool habitats in pipe storage yards by at least 250 feet or would remove a pipe yard from further consideration if vernal pool habitat is documented during future surveys (see Conservation Measures, below), no direct impacts to known large-flowered wooly meadowfoam are anticipated from use of pipe storage yards in Jackson County. Surveys conducted in suitable vernal pool habitat along the construction right-of-way between MPs 145.3 and 145.4 did not locate large-flowered woolly meadowfoam plants; therefore, no direct effects to large-flowered meadowfoam along the construction right-of-way are expected.

Indirect effects to large-flowered woolly meadowfoam and their habitat could occur with increased road use to access the pipe storage yards, as well as pipe storage yard activities, that are adjacent or near suitable or potentially suitable habitat. Although increased road use on paved Agate Road is not expected to increase fugitive dust, pipe yard activities and the associated dust created might impact vernal pool habitat within 250 feet of activities as dust settles, affecting vegetation and vernal pool physical or chemical properties (e.g., pH, water quality, turbidity, sedimentation, temperature). Increased dust levels can negatively impact plants by clogging stomatal openings in the leaves, impeding gas exchange and reducing the ability of plants to take in carbon dioxide. Dust on the leaf surface can also effectively reduce light availability at the leaf surface and thereby reduce plant growth and seed production.

Project use of pipe storage yards adjacent to, or within 250 feet of, suitable or potentially suitable habitat may also indirectly affect the hydrology upon which vernal pools and associated vegetation are dependent (e.g., through potential soil compaction from heavy equipment use). Indirect effects to hydrology could be expected within 250 feet of suitable or potentially suitable vernal pool habitat (see FWS 2011h). Effects could include altering hydrologic processes, such as runoff patterns because of soil compaction, as well as the potential for increased non-native invasive plant species. Any potential compaction that may occur at the yard would likely be insignificant because of the previous industrial use of these areas and associated soil grading. Based on topographic maps, flow patterns in the area are to the northwest, away from the 36 large-flowered woolly meadowfoam plants documented in 2007 and over 1,500 feet east of Burrill Lumber pipe storage yard, and no indirect impact to these plants from hydrologic impact would be anticipated. Additionally, any westerly flow from the Burrill Lumber pipe yard into critical habitat unit RV6C would be intercepted by the raised roadbed of paved, Agate Road.

No other direct or indirect effects to potential vernal pools are expected from use of unsurveyed pipe storage yards in Jackson County, including 0.48 acre of potential vernal pool wetlands (and 15.55 acres of vernal pool complex) identified from off-site observations within or adjacent to Avenue F & 11th Street and WC Short pipe yards (see table 3.6.1-1). Although a drainage has been identified on the north and west edges of Avenue F & 11th Street pipe yard, Pipeline use, if any, would be located farther than 250 feet from the potential vernal pool habitat.

Implementation of conservation measures included in section 3.7.3.4 would minimize impacts to potential suitable vernal pool habitat and large-flowered woolly meadowfoam plants, if present.

Cumulative Effects

Outside of the areas surveyed for the Pipeline, it is unknown where large-flowered woolly meadowfoam occurs on lands not under federal jurisdiction. Therefore, because the extent of this species on these non-federal lands is unknown, it is uncertain if there are reasonably foreseeable actions that might occur on these lands within areas currently occupied by this species. As the FWS's authority generally does not extend to listed plants on private or state lands,[15] all federally listed plants located on these lands must be considered at risk of adverse effects from potential developments. However, populations of large-flowered woolly meadowfoam and their habitats do have the potential to be protected on private and state lands as developments that could potentially affect vernal pool habitat would be required to comply with COE and ODSL requirements, which would limit potential cumulative effects to this species. Additionally, as approximately 98 percent of known large-flowered woolly meadowfoam populations occur in designated critical habitat, these populations may be protected regardless of land ownership. Other reasonably foreseeable projects on non-federal lands that could adversely affect this species include residential, commercial, and industrial development, as well as expanding agricultural areas.

PCGP has committed to implementing mitigation measures for this and other listed plant species regardless of land ownership.

Critical Habitat

One designated critical habitat subunit (RV6C) is located approximately 100 feet west of Burrill Lumber pipe storage yard across existing paved, Agate Road; no direct impacts due to the Pipeline are anticipated because equipment and pipe storage would not occur near or in pools or wetlands located in the critical habitat subunits, nor would traffic to and from the pipe storage yards drive near or in pools within the critical habitat unit. Additionally, plant sites previously located in critical habitat unit RV6C are over 100 feet from the proposed Burrill Lumber storage yard (Friedman 2006; ORBIC 2017c); therefore, no direct impact to those plant sites are expected. Another subunit, RV6D is located approximately 590 feet (at its closest point) northeast of Burrill Lumber pipe storage yard, where survey efforts in 2007 located large-flowered woolly meadowfoam. WC Short, Avenue F and 11th Street, and Rogue Aggregates proposed pipe yards are all over 1,500 feet from the nearest designated critical habitat units (see figure 3.7.3-1); no direct impacts to any designated critical habitat or plants from use of those pipe storage yards would occur.

Indirect effects to the designated critical habitat units in the vicinity of the four pipe storage yards proposed in Jackson County may occur as a result of increased road use to access the pipe storage yards that are adjacent to the critical habitat units (i.e., Agate Road) and use of Burrill Lumber pipe storage yard that is within 100 feet of critical habitat subunit RV6C. Although

[15] The ESA does not protect plants outside federal land unless there is a federal nexus. Therefore, activities that occur on private or state lands that could affect listed plants but which do not have federal nexus are not required to consult with the FWS. Plants may not be removed from lands under federal jurisdiction, and activities with a federal nexus must consult with the FWS.

increased road use on paved Agate Road is not expected to increase fugitive dust, potential dust created from use of the Burrill Lumber pipe yard might impact large-flowered woolly meadowfoam critical habitat as dust settles, affecting associated vegetation and vernal pool physical or chemical properties (e.g., pH, water quality, turbidity, sedimentation, and temperature). PCE 1 specifies that at least 20 acres are essential for intact hydrology, and impact to hydrology within critical habitat subunit RV6C may be expected if actions in the Burrill Lumber pipe storage yard alter hydrology within 250 feet (FWS 2011h). For example, use of the Burrill Lumber yard that includes ground disturbance such as soil compaction by heavy machinery may alter hydrology in vernal pools within critical habitat subunit RV6C, possibly affecting the frequency or amount of water in adjacent vernal pools, thereby altering the hydrology upon which vernal pools and associated vegetation are dependent. However, RV6C is separated from the Burrill Lumber pipe yard by 100 feet and the raised roadbed of Agate Road; therefore, it is highly unlikely that hydrology within RV6C would be impacted by use of the Burrill Lumber pipe storage yard. Additionally, the use of the roads adjacent to the critical habitat units and the pipe storage yards may increase the introduction of non-native, weedy species. PCE 4 specifies that no or negligible presence of competitive nonnative invasive plant species be present for the continued survival and recovery of large-flowered woolly meadowfoam.

Critical habitat unit RV8 is located greater than 1.4 miles from proposed pipe storage yards in Jackson County (see figure 3.7.3-1). The Pipeline project is not expected to directly or indirectly affect this critical habitat unit

Applying the conservation measures identified below, the use/alteration/restoration of pipe storage yards should not result in modifications in the timing, duration, magnitude, or quality of hydrological connections to an off-site vernal pool and/or large-flowered woolly meadowfoam. Additionally, measures taken to minimize the introduction and spread of noxious weeds outlined in the *Integrated Pest Management Plan* (appendix N to the POD) would reduce the risk of spreading or establishing new nonnative weed species.

3.7.3.4 Conservation Measures

PCGP has eliminated from further consideration the following previously proposed pipe storage yards to avoid potential effects to high-quality vernal pool habitat: Avenue C and 7th Street-Elite Cabinet & Door, Medford Industrial Park, and a portion of the previously delineated Burrill Lumber yard that included high quality vernal pool habitat east of the currently proposed yard. To avoid impacts to potential vernal pool habitat, as well as potential large-flowered woolly meadowfoam plants that may occur, although unlikely, along the northern and western edge of Avenue F and 11th Street pipe yard, PCGP would avoid using portions of Avenue F and 11th Street pipe storage yard within 250 feet of potential vernal pool habitat (boundary of indirect effects) or no longer pursue use of the pipe yard.

PCGP would install sedimentation control barriers, as recommended in the Recovery Plan (FWS 2012h) to minimize the potential for offsite mobilization of surface flows or sediment. As described in section 3.6.1.4 for vernal pool fairy shrimp, a silt fence would be erected on the west side of the right-of-way within 250 feet of vernal pools located between MPs 145.27 and 145.44. Additional potential mitigation measures considered for large-flowered woolly meadowfoam, if identified in the area, would include implementation of stormwater measures outlined in the ECRP (see appendix F) to reduce the potential for increased sediment mobilization as well as erosion and dust control measures listed in the ECRP to minimize fugitive dust along the construction right-of-way or within pipe storage yards, and BMPs in the Integrated Pest Management Plan (appendix N to the POD) to control existing noxious weeds and prevent new infestations within and adjacent to occupied and potential habitats.

3.7.3.5 Determination of Effects

Species

The Project **may affect** large-flowered woolly meadowfoam because:

- the Pipeline project occurs in the vicinity of occupied, large-flowered woolly meadowfoam habitat.

The Project is **not likely to adversely affect** large-flowered woolly meadowfoam because:

- surveys of potentially suitable habitat at proposed pipe storage yards in Jackson County and along the proposed Pipeline did not document large-flowered meadowfoam plants;
- PCGP would avoid using portions of proposed pipe storage yards within 250 feet (indirect effect) of these plant species or potentially suitable vernal pool habitat;
- effects to suitable habitat by the proposed action are likely to be insignificant to the point where no meaningful measurement, detection, or evaluation of impact would be possible (i.e., impact would not reach a level where individual plants would be lost);
- sedimentation barriers would be used, as appropriate, to prevent run-off and changes in hydrology;
- conservation measures have been developed to avoid or minimize impacts to future plants identified during surveys prior to construction; and
- construction of the Pipeline is not expected to adversely modify hydrology in nearby suitable habitat areas within 250 feet of proposed pipe storage yards.

Critical Habitat

The Project **may affect** designated critical habitat for large-flowered woolly meadowfoam because:

- the Project occurs adjacent to and nearby large-flowered woolly meadowfoam designated critical habitat.

A **not likely to adversely affect** determination is warranted for large-flowered woolly meadowfoam critical habitat because:

- construction of the Pipeline is not expected to adversely modify designated critical habitat areas within 250 feet of components of the Pipeline (i.e., subunit RV6C); existing features (i.e., paved Agate Road) and proposed conservation measures would provide sufficient protection from adjacent development and weed sources. The Burrill Lumber pipe yard is hydrologically disconnected from RV6D due to topography (flow is away from RV6D) and distance (greater than 590 feet), and is hydrologically isolated from RV6C by the raised Agate Road; and

- no dust-related impacts from use of the Burrill Lumber pipe storage yard would be expected because PCGP would implement measures in the Dust plan (see appendix B of the POD) to minimize potential impacts from fugitive dust.

3.7.4 Cook's Lomatium

Cook's lomatium (*Lomatium cookii*) is a perennial plant of the parsley (Apiaceae) family. It occurs 1) along vernal pools in the Agate Desert area of the Rogue River Valley in Jackson County, Oregon, and 2) in alluvial floodplains within the Illinois River Valley area near Cave Junction in Josephine County, Oregon (FWS 2006f).

3.7.4.1 Species Account and Critical Habitat

Status

Cook's lomatium was listed as endangered on November 7, 2002 (FWS 2002b). In 2010, the FWS designated critical habitat for Cook's lomatium (and concurrently for large-flowered woolly meadowfoam; FWS 2010c).

Threats

A major factor in the FWS 2002 listing of Cook's lomatium was the present or threatened destruction, modification, or curtailment of its habitat (vernal pools) and range. The primary threats to habitat and range are industrial, commercial, and residential development and their associated road and utility construction and maintenance. The FWS also found that competition from introduced grass species and grazing can reduce or eliminate populations (FWS 2002b). In addition, vandalism, in the form of intentional disregard or dismantling of signage or fencing intended to protect certain wetland areas from unauthorized OHV use, and subsequent damage resulting from that use, has resulted in negative effects to habitat.

Grazing can have a mixed effect on Cook's lomatium. The effect of grazing on suitable habitat depends on how the grazing is managed. There are various reports showing how grazing practices can positively or negatively affect native plant species' richness. The Marty (2005) study indicates that wet season grazing resulted in a decrease of native forb species at vernal pool edge habitat, but year-round improved species' richness.

Although disease (e.g., fungal infections) and herbivory have been identified as potential problems, no data other than casual observations exist to suggest that these factors pose a current substantial threat to the species (FWS 2012h). Because of continuing population and development pressures on the limited Cook's lomatium habitat and range, the factors cited in the listing decision remain as significant ongoing threats to the species.

Species Recovery

In November 2012, the FWS (2012h) finalized the *Recovery Plan for Rogue and Illinois Valley Vernal Pool and Wet Meadow Ecosystems* (FWS 2012h). It identifies nine core areas for protection of vernal pool dependent species in the Rogue Valley, including Cook's lomatium. The recovery objectives specific for Cook's lomatium include:

- At least 32 of 36 occurrences for Cook's lomatium (approximately 90 percent of documented/extant occurrences) should be protected from development. For occurrences that have become extirpated, reintroduced or introduced populations may be substituted. Introduced or newly discovered populations outside of currently known core areas may be substituted if the FWS deems them equivalent in their contribution to recovery.

- At least 90 percent of suitable vernal pool habitat acreage within the four Priority 1 core areas for the species and at least 85 percent of suitable vernal pool habitat acreage within the five Priority 2 core areas for the species has been protected from development. All suitable habitat must include soils and hydrology that support the plant species.
- Additional species occurrences identified through future site assessments, GIS, other analyses, or status surveys, and that are determined essential to recovery, are protected.
- Seeds from each core area should be collected and stored as insurance against the risk of extirpations and to ensure that genetic lines are preserved. Seed banking is also necessary to complete the reintroductions or introductions that can contribute to meeting recovery criteria.

Life History, Habitat Requirements, and Distribution

Cook's lomatium is a small perennial in the parsley family. Its range is on seasonally wet soils limited to two areas: 1) along vernal pools in the Agate Desert area of the Rogue River Valley in Jackson County, and 2) in alluvial floodplains within the Illinois River Valley area near Cave Junction in Josephine County (FWS 2006f).

The Jackson County populations occur along the margins and bottoms of vernal pool habitats within the 20,510-acre Agate Desert. Located on the floor of the Rogue River basin north of Medford, the Agate Desert is characterized by shallow, Agate-Winlo complex soils, a relative lack of trees, sparse prairie vegetation, and agates commonly found on the soil surface. Fire may maintain suitable habitat because shrubs compete for sun and space, and a historical fire regime is thought to have prevented such shrubs from encroaching on Cook's lomatium habitat (FWS 2006f). Cook's lomatium plants in the Agate Desert are found on the margins and bottoms of vernal pools with standing water from December to April or May. The plant flowers from late March to May and is pollinated entirely by insects. Each flowering stalk produces either primarily male or female flower clusters (FWS 2006f). In the Rogue River Valley, Cook's lomatium is found in the same vernal pool habitats as the large-flowered woolly meadowfoam and the vernal pool fairy shrimp.

The Josephine County populations occur on seasonally wet soils in the Illinois Valley. The Pipeline project is not located in Josephine County, and this population and habitats are not discussed further.

Population Status

Cook's lomatium occupies 146.5 acres in the Rogue Valley's Agate Desert; an estimated 4,086 acres of potential Cook's lomatium habitat is present within the area. In the Rogue Valley, Cook's lomatium is known from 13 occurrences, of which six are extant, six are unknown in status, and one is extirpated; the Cook's lomatium total population in the Rogue Valley is estimated at 34,000 plants (FWS 2012h).

Critical Habitat

Critical habitat for Cook's lomatium was designated on July 21, 2010, including three critical habitat units in Jackson County, totaling 924 hectares (2,282 acres) (FWS 2010c). As the Pipeline occurs within and adjacent to the Agate Desert complex, this analysis focuses on the Agate Desert geographic area.

When determining areas for critical habitat for the Cook's lomatium in the Agate Desert, FWS focused on the biological or physical PCEs that are essential to the conservation of the species. The PCEs for Cook's lomatium critical habitat include:

1. vernal pools or ephemeral wetlands and the adjacent upland margins of these depressions that hold water for a sufficient length of time to sustain Cook's lomatium, growth, and reproduction, between elevations of 1,256 to 1,600 feet, a minimum of 20 acres, and associated with specific dominant native plants (FWS 2010c);
2. the hydrologically and ecologically functional system of streams, slopes, and wooded systems that surround and maintain seasonally wet alluvial meadows underlain by relatively undisturbed ultramafic soils within the greater watershed;
3. silt, loam, and clay soils that are of ultramafic and nonultramafic alluvial origin, with a 0 to 40 percent slope, classified as Abegg gravelly loam, Brockman clay loam, Copsey clay, Cornutt–Dubakel complex, Dumps, Eightlar extremely stony clay, Evans loam, Foehlin gravelly loam, Josephine gravelly loam, Kerby loam, Newberg fine sandy loam, Pearsoll–Rock outcrop complex, Pollard loam, Riverwash, Speaker–Josephine gravelly loam, Takilma cobbly loam, or Takilma Variant extremely cobbly loam; and,
4. no or negligible presence of competitive, nonnative, invasive plant species.

Sixteen critical habitat units (CHU) have been designated for the Cook's lomatium; 3 in Jackson County, of which two units (White City and Whetstone Creek) are shared by the designated critical habitat for large-flowered woolly meadowfoam (FWS 2010c).

3.7.4.2 Environmental Baseline

Analysis Area

For most listed plant species, the botanical analysis area extends to 30 meters (98 feet) each side of the Pipeline project (construction right-of-way, TEWAs, UCSAs, rock source and disposal sites, and proposed storage yards) on lands that have potential habitat for listed plant species. This area generally corresponds to the extent of the area surveyed for sensitive and listed plant species during surveys conducted between 2007 and 2017 (at least 100 feet from habitat removal on federal lands and at least 50 feet from habitat removal on non-federal, private lands), and correlates to a distance that indirect effects to plants would be expected. For the Cook's lomatium, the analysis area was extended 250 feet from the perimeter of four proposed pipe storage areas that are located within the Vernal Pool Complex – Agate Desert, Jackson County, Oregon and shown in figure 3.7.4-1, as well as 250 feet from the Pipeline right-of-way in the vicinity of Agate-Winlo soil complex. This is a distance within which indirect effects from the Proposed Action could occur to vernal pools supporting this species (FWS 2011h).

Species Presence

Within the vicinity of the Pipeline project, Cook's lomatium is known to occur within the Agate Desert, and is associated with Agate-Winlo soils in Jackson County, Oregon. Multiple locations of Cook's lomatium have been documented in the Agate Desert, in and around White City, Jackson County; these locations are in proximity to proposed pipe storage yard locations. One population is located 10.3 miles west of the Pipeline route near MP 145.7 (ORBIC 2017c), and several occurrences of Cook's lomatium have been documented 0.5 mile south of the proposed Avenue F & 11th Street, and WC Short yards in the Ken Denman State Game Management Reserve (Hall Tract Unit; Friedman 2006; ORBIC 2017c; see figure 3.7.4-1). Lands between the proposed yards and the Cook's lomatium occurrences are developed with multiple industrial sites on both sides of Antelope Road. No populations of Cook's lomatium were identified by PCGP at any of its proposed facilities; however, some suitable habitat exists near proposed pipe storage yards, as discussed below.

Project-Specific Surveys

Habitat Surveyed. Prior to beginning field surveys in 2007, botanists with SBS conducted a habitat review to identify potential habitat and delineate survey areas for Cook's lomatium within the botanical analysis area, including existing roads identified for access to the construction right-of-way, and associated impact areas like pipe storage yards. Aerial photographs and knowledge of regional landscape and biological features (e.g., soils, geology, topography, elevation, target species habitat, and plant community habitat) were used to determine potential habitat for Cook's lomatium. These same methods were applied to determine areas of suitable habitat in new locations where the proposed right-of-way and related facilities have been relocated or altered since 2007. Habitat found to be "suitable" in the surveys included areas with some of the characteristics detailed in the Life History, Habitat Requirements, and Distribution section under section 3.7.3.1.

Four pipe storage yards have been proposed within the Agate Desert near White City in Jackson County in proximity to known occupied vernal pools and designated Cook's lomatium critical habitat: Burrill Lumber, WC Short, Ave F & 11th St, and Rogue Aggregates (see figure 3.7.4-1). With the exception of Rogue Aggregates, all pipe yards proposed occur on Agate-Winlo complex soils. Although the pipe storage yards are within existing industrial sites, protected vernal pools could be present that may provide potential vernal pool habitat for Cook's lomatium. Where survey access was permitted, habitat within the pipe yards was evaluated to identify suitable vernal pool habitat for Cook's lomatium (see table 3.6.1-1).

In 2007, SBS identified vernal pool habitat in and near possible pipe storage yards in Jackson County that could provide habitat for Cook's lomatium. Surveys for the Cook's lomatium, as well as large-flowered woolly meadowfoam (see section 3.7.3), occurred in the proposed Burrill Lumber pipe yard and Rogue Aggregates pipe yard in 2007; no vernal pools were identified in the two proposed pipe storage yards and no plants were observed. In 2018, habitat north of Burrill Lumber was assessed off-site to determine if possible vernal pools were present within 250 feet of the yard. Based on observations from Agate Road and review of aerial photography, no potential vernal pools are located within 250 feet of the Burrill Lumber pipe yard. Although Rogue Aggregates pipe yard has been reconfigured since surveys in 2007, portions not included in previous survey efforts for the Pipeline project are not expected to provide suitable habitat for Cook's lomatium because they do not contain suitable soil types.

No surveys within Avenue F & 11th Street and WC Short pipe storage yards have been permitted. Based on aerial photography and off-site observation in April 2018, Avenue F and 11th and WC Short pipe yards do not contain vernal pools. Avenue F and 11th pipe yard is highly disturbed and graded, with railroad and docking faciltities located on the southern edge of the yard, and WC short pipe yard is an existing train yard that would assist moving and off-loading pipe. Although no vernal pools have been observed in Avenue F and 11th pipe yard, there is a long drainage ditch that runs along the northern edge of the pipe yard and paved Avenue F road and extends south along the western edge of the yard and could provide habitat for Cook's lomatium. The drainage has very little movement and could be considered low quality vernal pool habitat (approximately 0.46 acre). No potential vernal pools have been identified in WC Short, and two small exposed drainage ditches (0.02 acre), in an otherwise underground piped drainage system, experience occasional high flow. They are located along an existing access road (Avenue G) within WC Short pipe yard and would not provide suitable vernal pool habitat for Cook's lomatium.

In 2007, a much larger area previously considered for the Burrill Lumber pipe storage yard was also evaluated. High quality suitable vernal pool habitat (approximately 4.4 acres) was observed 850 to 1,165 feet east of the currently proposed Burrill Lumber storage yard where 36 large-flowered woolly meadowfoam were documented in 2007; no Cook's lomatium plants were documented (SBS 2008a). Additionally in 2007, two other pipe yards that are no longer included for the proposed Pipeline project were evaluated (11 acres of suitable vernal pool habitat were observed and surveyed south of Ave F & 11th Street pipe yard within Avenue C and 7th Street pipe yard [10.5 acres in seven seasonally saturated pools] and north of Ave F & 11th Street pipe yard within the Medford Industrial Park pipe yard [0.55 acre in 20 seasonally saturated pools; see figure 3.7.4-1]). Although suitable vernal pool habitat was present, no plants were observed (SBS 2008a).

Nine vernal pools (totaling approximately 0.2 acre) within and adjacent to the Pipeline right-of-way on private lands (between MPs 145.3 and 145.40) that occur on Agate-Winlo soils were surveyed in 2007 for presence of vernal pool special status species, including Cook's lomatium; no plants were documented (SBS 2008a).

Approximately 190.29 acres within 250 feet of proposed pipe storage yards, including Avenue F & 11th Street and WC Short pipe yards in Jackson County have not been evaluated on-site for vernal pool habitat; off-site observations identified approximately 0.48 acre of highly modified, low quality vernal pool habitat within 250 feet of proposed pipe. Approximately 0.48 acre of potential vernal pool habitat has not been surveyed on-site for Cook's lomatium; the area is associated with active industrial sites or previously disturbed industrial areas but could provide low quality habitat for Cook's lomatium (table 3.6.1-1).

Survey Results. No populations of Cook's lomatium were identified during Pipeline survey efforts.

Critical Habitat

Within the vicinity of White City, Oregon, where four proposed pipe storage yards for the Pipeline project are located, CHUs RV6 and RV8 have been designated (see figure 3.7.4-1). One of the 16 designated critical habitat units for Cook's lomatium (RV6) has two subunits located approximately 0.5 miles south (RV6A) and 0.8 mile southeast (RV6H) of the proposed Avenue F and 11th Street and WC Short pipe storage yards. Another critical habitat unit (RV8) is located approximately 1.8 miles east of Rogue Aggregates pipe yard.

3.7.4.3 Effects of the Proposed Action

Direct and Indirect Effects

Possible direct effects to Cook's lomatium include disturbance to pools from driving through or storing equipment or pipes near or on pools or wetlands associated with this species. Direct effects to Cook's lomatium and its habitat could be expected in vernal pools and upland habitat within 100 feet from delineated vernal pool habitat. Because no vernal pool habitat has been documented in surveyed (onsite) Jackson County proposed pipe storage yards (Burrill Lumber and Rogue Aggregates), and pipe yards have been removed and/or reconfigured in Jackson County to avoid potentially suitable vernal pool habitats, and because PCGP has committed to avoiding vernal pool habitats in pipe storage yards by at least 250 feet or would remove a pipe yard from further consideration if vernal pool habitat is documented during future surveys (i.e., Avenue F and 11th Street pipe yard; see Conservation Measures, below), no direct impacts to Cook's lomatium or its habitat is anticipated. Surveys conducted in suitable vernal pool habitat along the construction right-of-way between MPs 145.3 and 145.4 did not locate Cook's lomatium plants; therefore, no direct effects to Cook's lomatium along the Pipeline right-of-way are expected.

Indirect effects to Cook's lomatium plants and their habitat could occur with increased road use to access the pipe storage yards, as well as pipe storage yard activities, that are adjacent or near suitable or potentially suitable habitat. Although increased road use on paved Agate Road is not expected to increase fugitive dust, pipe yard activities and the associated dust created might impact vernal pool habitat located within 250 feet of activities as dust settles, affecting vegetation and vernal pool physical or chemical properties (e.g., pH, water quality, turbidity, sedimentation, temperature). Use of pipe storage yards adjacent to, or in the vicinity of suitable or potentially suitable habitat, may indirectly affect hydrology (i.e., potential soil compaction by heavy equipment use) upon which vernal pools and associated vegetation are dependent, although this potential effect is highly unlikely. Indirect effects to hydrology could occur if such disturbances to ground and/or soils occurred within 250 feet of suitable or potentially suitable vernal pool habitat (FWS 2011h). Such effects could include altering hydrologic processes, such as runoff patterns as a result of soil compaction, as well as introduction of non-native invasive plant species (PCEs 1 and 4).

No other direct or indirect effects to potential vernal pools are expected from use of unsurveyed pipe storage yards in Jackson County, including 0.48 acre of potential vernal pool wetlands (and 15.55 acres of vernal pool complex) identified from off-site observations within or adjacent to Avenue F & 11th Street and WC Short pipe yards (see table 3.6.1-1). Although a drainage has been identified on the north and west edges of Avenue F & 11th Street pipe yard, Pipeline use, if any, would be located farther than 250 feet from the potential vernal pool habitat.

Implementation of conservation measures included in section 3.7.4.4 would minimize impact to potential suitable vernal pool habitat and Cook's lomatium plants, if present.

Cumulative Effects

Outside of the areas surveyed for the Pipeline, it is unknown where Cook's lomatium occurs on lands not under federal jurisdiction. Therefore, because the extent of this species on these non-federal lands is unknown, it is uncertain if there are reasonably foreseeable actions that might occur on these lands within areas currently occupied by this species. As the FWS's authority generally does not extend to listed plants on private or state lands,[16] all federally listed plants located on these lands must be considered at risk of adverse effects from potential developments. However, populations of Cook's lomatium and their habitats do have the potential to be protected on private and state lands as developments that could potentially affect vernal pool habitat would be required to comply with COE and ODSL requirements, which would limit potential cumulative effects to this species. Other reasonably foreseeable projects on non-federal lands that could adversely affect this species include residential, commercial, and industrial development, as well as expanding agricultural areas.

PCGP has committed to implementing mitigation measures identified for listed plants regardless of land ownership.

Critical Habitat

Critical habitat subunit RV6A is approximately 0.5 mile south of the Avenue F & 11th Street and WC Short proposed pipe storage yards, and critical habitat unit RV8 is more than 1.8 miles from the proposed pipe storage yards in Jackson County. Given the distance separating the pipe storage yards and RV6A and RV8, no direct or indirect impacts from the Pipeline are anticipated since equipment and pipe storage would not occur within 250 feet of pools or wetlands located in the critical habitat subunit, nor would traffic to and from the pipe storage yards drive within 250 feet of vernal pools within the critical habitat unit.

Applying conservation measures identified below, and use/alteration/restoration of pipe storage yards should not result in modifications in the timing, duration, magnitude, or quality of hydrological connections to an off-site vernal pool and/or Cook's lomatium within critical habitat units. Additionally, measures taken to minimize the introduction and spread of noxious weeds outlined in the *Integrated Pest Management Plan* (appendix N to the POD) would ensure that competition from nonnative species in critical habitat units within the vicinity of proposed pipe yards remains negligible.

3.7.4.4 Conservation Measures

PCGP has eliminated from further consideration the following previously proposed pipe storage yards to avoid potential effects to high-quality vernal pool habitat: Avenue C and 7th Street-Elite Cabinet & Door, Medford Industrial Park, and a portion of the previously delineated Burrill

[16] The ESA does not protect plants outside federal land unless there is a federal nexus. Therefore, activities that occur on private or state lands that could affect listed plants but which do not have federal nexus are not required to consult with the FWS. Plants may not be removed from lands under federal jurisdiction, and activities with a federal nexus must consult with the FWS.

Lumber yard that included high quality vernal pool habitat east of the currently proposed yard. To avoid impacts to potential vernal pool habitat, as well as potential Cook's lomatium plants that may occur along the northern and western edge of Avenue F and 11th Street pipe yard, PCGP would avoid using portions of Avenue F and 11th Street pipe storage yard within 250 feet of potential vernal pool habitat (boundary of indirect effects) or no longer pursue use of the pipe yard.

If Cook's lomatium is observed within proximity to the pipe storage yards or the construction corridor, PCGP would insall sedimentation control barriers as recommended in the Recovery Plan (FWS 2012h) to minimize potential impacts to identified Cook's lomatium plants and highly suitable habitat from erosion of sedimentation. As described in section 3.6.1.4 for vernal pool fairy shrimp, a silt fence would be erected on the west side of the right-of-way within 250 feet of vernal pools located between MPs 145.27 and 145.44. Additional mitigation measures considered for Cook's lomatium, if identified in the area during surveys, would include implementation of additional stormwater BMPs outlined in the ECRP (appendix F) to reduce and mitigate the potential for increased sediment mobilization as well as erosion and dust control measures listed in the ECRP and BMPs in the Integrated Pest Management Plan (appendix N to the POD) to control existing noxious weeds and prevent new infestations within and adjacent to occupied and potential habitat.

3.7.4.5 Determination of Effects

Species

The Project **may affect** Cook's lomatium because:

- suitable, occupied habitat occurs within the vicinity of the Pipeline project.

The Project is **not likely to adversely affect** Cook's lomatium because:

- surveys of suitable habitat at proposed pipe storage yards in Jackson County and along the proposed Pipeline did not document Cook's lomatium;
- PCGP would avoid using portions of proposed pipe storage yards within 250 feet (indirect effect) of these, as well as areas with potential vernal pool habitat;
- effects to suitable habitat by the proposed action are likely to be insignificant to the point where no meaningful measurement, detection, or evaluation of impact would be possible (i.e., impact would not reach a level where individual plants would be impacted);
- sedimentation barriers would be used, as appropriate, to prevent run-off and changes in hydrology;
- conservation measures have been developed to avoid or minimize impacts to future plants identified during surveys prior to construction;
- known sites within the vicinity of the project are farther than 0.5 mile from proposed pipe storage yards; and
- unsurveyed habitat is low quality vernal pool habitat located over 0.25 mile from known sites with no apparent hydrologic connectivity.

Critical Habitat

The Project **may affect** designated critical habitat for Cook's lomatium because:

- the Project occurs in the vicinity of Cook's lomatium critical habitat.

The Project would have **no effect** on designated critical habitat for Cook's lomatium because:

- the Pipeline is over 0.5 miles from the nearest critical habitat subunit RV6A; and
- the Pipeline is not expected to adversely modify habitat areas that provide buffer protection from adjacent development and weed sources, continuous non-fragmented habitat, and intact hydrology (PCEs 1 and 4).

3.7.5 Kincaid's Lupine

Kincaid's lupine (*Lupinus oreganus* ssp. *kincaidii*) is a perennial plant species related to the pea (Fabaceae) family. It is known from grassland habitats, mainly in the Willamette Valley and nearby hills, in Oregon, although in Douglas County it occupies sites that are more shaded with tree and shrub canopy (FWS 2006g).

3.7.5.1 Species Account and Critical Habitat

Status

Kincaid's lupine was listed as threatened on January 25, 2000 (FWS 2000c). Approximately 600 acres of critical habitat was designated for this species in 2006 within Oregon and Washington (FWS 2006g).

Threats

The three major threats to Kincaid's lupine populations are habitat loss, competition from non-native plants, and elimination of historical disturbance regimes, such as fire (Wilson et al. 2003; FWS 2010d). The present or threatened destruction, modification, or curtailment of the Kincaid's lupine habitat and range was a major factor for the FWS listing in the final rule. Human alteration of the plant's native prairie in Oregon's Willamette Valley has destroyed over 99 percent of its habitat (FWS 2000c). Remaining prairie habitat is rapidly disappearing because of agricultural practices, development activities, forestry practices, grazing, roadside maintenance, and commercial Christmas tree farming (FWS 2000c). The remaining Kincaid's lupine populations in prairie habitat are relegated to small, isolated patches of habitat. Habitat loss could continue as private lands are developed.

Most prairie sites require frequent disturbances to hold back the natural succession of trees and shrubs. Before settlement by Euro-Americans, the regular occurrence of low-severity fire maintained the open prairie habitats essential to Kincaid's lupine. The loss of a regular disturbance regime has resulted in the decline of prairie habitats through succession by native trees and shrubs, and has allowed the establishment of numerous non-native grasses and forbs. At the time of federal listing, 83 percent of upland prairie Kincaid's lupine sites were estimated to be succeeding to forest (FWS 2000c, 2008e).

In Douglas County, Kincaid's lupine has been found in open woodlands and meadows, often near roads, and associated with Pacific madrone, incense cedar, and Douglas-fir with open canopies (FWS 2008e). Those populations appear to tolerate more shade than populations in the Willamette Valley (BLM et al. 2008). Kincaid's lupine habitat in forested sites is subject to similar alterations from natural succession; fire suppression activities result in increased canopy closure and cover of woody species that contribute to the decline in Kincaid's lupine forested habitat (FWS 2006g).

The Willamette Valley continues to be an important population center for urban, rural, transportation, commercial, and agricultural activities. Aside from changes in fire regimes, other ongoing threats include further habitat loss or fragmentation due to agriculture, development, and forest practices; herbicide use; disease and predation; invasion of prairie habitats by non-native species; inbreeding as a result of isolated and fragmented populations; and habitat vandalism (which is an uncommon occurrence but could further reduce habitat function and destroy individual plants; FWS 2008e, 2010d). Changes in the natural hydrology of a site, such as by ditching or draining a wet prairie can alter the annual duration of soil saturation, which can in turn affect the species composition of the site. Hydrological alterations have been a factor in the reduction of native species in the Willamette Valley (Finley 1995 in FWS 2010d).

Species Recovery

A final recovery plan for the prairie species of western Oregon, including Kincaid's lupine, was published on January 1, 2010, and includes recovery objectives to delist Kincaid's lupine (FWS 2010d). Ten recovery zones were established for Kincaid's lupine, of which Douglas County is considered its own recovery zone. Since the clonal or clumping growth pattern of Kincaid's lupine creates a challenge for estimating and monitoring the number of plants, the recovery plan provides population targets in terms of foliar cover (i.e., the measure of the area occupied by the plants).

Within Douglas County through which the Pipeline will pass, the Douglas County Recovery Zone has a recovery goal of a minimum of two populations covering at least 5,000 square meters (1.25 acres), which are not separated by more than 2.0 miles (FWS 2010d); in 2010, populations were estimated to cover approximately 1.2 acres (FWS 2010e). Additionally, monitoring of these populations should show evidence of reproduction by flowering, seed set, or presence of seedlings, and remain stable or increase in size for a period of at least 15 years. Habitat for Kincaid's lupine populations should be managed to provide high-quality habitat that is protected on lands managed by a government agency or private conservation agreement and is monitored and controlled from threats to the species (FWS 2010d). Recovery actions for Kincaid's lupine include:

- evaluate the status of extant populations;
- manage population sites to minimize woody plant succession and reduce the threat of competition from nonnative plants, including mowing in late summer (August or September) after the plants have become dormant, and elimination of invasive species with careful and appropriate application of herbicides or mechanical control methods;
- restore connectivity among populations, establishing subpopulations within 2 miles of each other;
- augment or reintroduce populations and restore habitat to achieve population targets;
- monitor populations and trends;
- monitor prairie quality at all population sites; and
- collect and bank seeds.

Life History, Habitat Requirements, and Distribution

Kincaid's lupine is a long-lived perennial herb inhabiting native prairies and foothills (FWS 2000c). Prior to Euro-American settlement, Kincaid's lupine was likely well-distributed throughout the prairies of western Oregon and southwestern Washington from Lewis County, Washington, in the north, to the foothills of Douglas County, Oregon, in the south. Today, fragmentation, degradation, and elimination of natural prairie habitat has resulted in existing populations that are widely separated by expanses of unsuitable habitat (FWS 2008e). Most of the known extant populations are found in Oregon's Willamette Valley (FWS 2006g).

In Douglas County, Kincaid's lupine appears to tolerate more shaded conditions, where it occurs at sites with canopy cover of 50 to 80 percent. Tree and shrub species dominating occupied sites include Douglas-fir, California black oak, Pacific madrone, ponderosa pine, incense cedar, hairy manzanita, and poison oak (FWS 2006g).

Kincaid's lupine reproduces sexually and asexually with production of rhizomes (horizontal stems) that can produce clumps of cloned plants. Individual clones can be several centuries old (FWS 2005g; Kaye 2008) and can become quite large with age, producing many flowering stems. Excavations and morphological patterns suggest that plants 33 feet or more apart can be interconnected by below-ground stems, and such clones can exceed 66 feet across. Because of vegetative (clonal) growth pattern, it is difficult to distinguish individuals (Wilson et al. 2003); counting individual "plants" and monitoring the size of populations is challenging. Instead, monitoring agencies have used a grid pattern and counted stems or leaves to assess density rather than attempt to count "individuals."

Flowering typically ranges from April through June. Pollinators include small native bumblebees, solitary bees, and occasionally European honey bees. Insect pollination appears to be critical for successful seed production. Seeds are dispersed from fruits that open explosively upon drying (FWS 2006g). Seeds of the genus *Lupinus* could lie dormant for many years because of their relative impermeability, with noted similar longevity to Scotch broom that could remain viable in the ground for up to 60 years (Grigore and Tramer 1996; CPOP 2014; JCNWCB 2014). Lupine seeds will germinate under increasing humidity or when the seed coat is cracked by pressure or temperature fluctuations (Grigore and Tramer 1996). Kincaid's lupine is also a host plant for the endangered Fender's blue butterfly (FWS 2008e). Fire is necessary to maintain and sustain habitat for the Fender's blue butterfly (FWS 2003). Also, fire clears shading vegetation, especially from invasive species, and converts soil phosphorous into a form more usable by plants. Kincaid's lupine may respond positively to fire (Wilson and Clark 1997) and fire may lead to increased numbers of pollinators which have a positive effect (FWS 2003).

Population Status

Most of the known extant populations are found in Oregon's Willamette Valley. At the time of listing, approximately 91 percent of the occupied sites (i.e., 51 of 54 sites) were on private lands and therefore were considered to be at a higher risk of extirpation (FWS 2008e). As of the 2010 five-year review, Kincaid's lupine is known to occur within about 164 sites, comprising about 246 hectares (608 acres; FWS 2010g). Another five-year review was initiated in February 2016 that will provide additional information on population status (FWS 2016f).

Critical Habitat

Almost 600 acres of critical habitat were designated on November 30, 2006, in Benton, Lane, Polk, and Yamhill Counties, Oregon, and Lewis County, Washington (FWS 2006g). The designation did not include Douglas County where conservation agreements were established to formally document the intent to protect, conserve, and contribute to the recovery by implementing recovery actions for Kincaid's lupine and its habitat (see further discussion below).

The PCEs of critical habitat are: 1) the habitat components that provide early seral upland prairie and oak savanna habitat with a mosaic of low growing grasses, forbs, and spaces to establish seedlings or new vegetative growth, with an absence of dense canopy vegetation providing sunlight for individual and population growth and reproduction; and 2) the presence of insect pollinators with available corridors between lupine patches to allow unrestricted movement of pollinators (FWS 2006g).

Other Conservation Agreements and Plans. In 2006, the BLM Roseburg District, Umpqua National Forest, and FWS completed a programmatic conservation agreement for Kincaid's lupine in Douglas County, which specifies the following goals (BLM et al. 2006):

1. Maintain stable populations by protecting and restoring habitats.
2. Reduce threats to the species on BLM and NFS lands.
3. Promote larger functioning meta-populations, with increased population size and genetic diversity.
4. Meet the recovery criteria in the Recovery Outline for the species (FWS 2006g).

Also in 2006, three private timber companies in Douglas County (Lone Rock Timber Management Company, Roseburg Forest Products, and Seneca Jones Timber Company) signed a voluntary conservation agreement. This *Voluntary Agreement for Kincaid's Lupine (*Lupinus Sulphureus *spp.* kincaidii*) in Douglas County* (Lone Rock Timber Management Company et al. 2006) includes reporting guidelines and an agreement for road maintenance and minimizing disturbance along roads. The objective of the Voluntary Agreement is "to promote functioning meta-populations," including coordinating propagation activities for establishing new sites and extending known populations.

In March 2008, a management plan for Kincaid's lupine in Douglas County was developed between the BLM's Roseburg District, the Umpqua National Forest, and the FWS addressing the populations and habitat of Kincaid's lupine on BLM and NFS lands in Douglas County (BLM et al. 2008). Kincaid's lupine occurs on 14 sites within Douglas County, of which 9 are on federally managed lands (8 on BLM land [Roseburg District] and 1 on the Umpqua National Forest; BLM et al. 2008).

3.7.5.2 Environmental Baseline

Analysis Area

The botanical analysis area extends to 30 meters (98 feet) each side of the Pipeline project (construction right-of-way, TEWAs, UCSAs, rock source and disposal sites, and proposed storage yards) on lands that have potential habitat for listed plant species. This area generally corresponds to the extent of the area surveyed for sensitive and listed plant species during surveys conducted between 2007 and 2017 (at least 100 feet from habitat removal on federal lands and at least 50 feet from habitat removal on non-federal, private lands), and correlates to a distance that indirect effects to plants would be expected. Portions of the botanical analysis area that coincide with Kincaid's lupine are included in figures 3.7.5-1, 3.7.5-2, and 3.7.5-3.

Species Presence

The Pipeline is located within known or historic Kincaid's lupine range between MPs 46.8 and 99.3. Records obtained from ORBIC (2017c) indicate that Kincaid's lupine had been previously located at 11 sites within 2.5 miles of the Pipeline. The closest sites are: 1) 10 clumps located 1.5 miles north of MP 56.0 in 1999 within a 200 square-foot area; 2) 100 to 1,000 plants located 1.5 miles southeast of MP 59.6 in 2005; 3) 100 to 1,000 plants located 2.0 miles northeast of MP 86 in 1990; 4) 400 to 4,000 plants within four sites occupying approximately 3 acres located 2.2 miles southwest of MP 96.0 in 2003; and 5) about 100 to 200 plants in one acre located in 1992 approximately 1.5 miles east of MP 98.9. Herbarium records indicate that one extinct population (1979) occurred near the 1992 documented site, approximately 1.7 miles east of MP 98.9 and 0.25 mile from the other 1992 population. Botanical surveys conducted by PCGP in 2007-2008 located three new populations of Kincaid's lupine along the Pipeline route, as discussed below.

Project-Specific Kincaid's Lupine Survey

Habitat Surveyed. Prior to beginning field surveys in 2007, botanists with SBS conducted a habitat review to identify potential habitat and delineate survey areas for Kincaid's lupine within the botanical analysis area from MPs 46.8 to 111.0, including existing roads identified for access to the construction right-of-way. Aerial photographs and knowledge of regional landscape and biological features (soils, geology, topography, elevation, target species habitat, and plant community habitat) were used to determine potential habitat for Kincaid's lupine. These same methods were applied to determine areas of suitable habitat in new locations where the proposed right-of-way has been relocated since 2007.

Surveys were conducted for this species where survey permission was granted within the vicinity of the Pipeline project (within at least 50 or 100 feet of the Pipeline project on non-federal and federal lands, respectively and where permitted) and along proposed access roads (within at least 50 feet of access roads where road improvements are proposed and surveys permitted). Most surveys were conducted in 2007 and 2008, but additional surveys have been conducted since 2008 in areas of reroutes, minor route adjustments, and areas with granted survey permission. Areas where Kincaid's lupine were documented during previous Pipeline survey efforts were also resurveyed in 2016 and/or 2017. Surveys have continued in 2018 and data are currently under review.

Overall, 2,840.88 acres have been surveyed by PCGP from 2007 through 2017 for Kincaid's lupine within the vicinity of the proposed Pipeline, including previously proposed routes and project components, alternate routes, and along access roads that are no longer considered for the Pipeline project. Within the 30-meter botanical analysis area, approximately 2,674.24 acres, generally between MPs 46 and 99.3, have been identified as potential suitable habitat (see table 3.7.5-1). The potential suitable habitat includes both meadow (typically non-native pasture) and forested upland Kincaid's lupine habitats. Of this habitat, access was granted to 1,682.62 acres (842.85 acres within the Pipeline project), including potential habitat within 50 feet of access roads where road improvements have been proposed. Table 3.7.5-1 provides a summary of potential suitable Kincaid's lupine habitat within the botanical analysis area.

Of the 1,682.62 acres of potential habitat with survey access, 1,273.77 acres (661.56 acres within the Pipeline project) were considered suitable habitat for Kincaid's lupine. Habitat suitability was qualitatively assessed based on Kincaid's lupine habitat analysis conducted in Oregon by SBS in 2001. Habitat found to be "suitable" in the surveys included areas with some of the characteristics detailed in the Life History, Habitat Requirements, and Distribution section above.

Approximately 991.62 acres (448.67 acres within the Pipeline project) of potentially suitable habitat for this species within the botanical analysis area was denied access by the landowner or occurs within recent modifications of the Pipeline project (the majority of this habitat occurs on non-federal lands; see table 3.7.5-1). PCGP would continue to survey habitat where permission is granted. Where survey access is denied, PCGP would conduct surveys in suitable habitat within the Pipeline project footprint prior to construction. For purposes of analysis, until surveys are conducted, a conservative assumption can be made that a similar percent of the unsurveyed area could contain suitable habitat. Based on this assumption, approximately 730 acres of habitat within the botanical analysis area (73.6 percent of 992 acres, or 330 acres within the Pipeline right-of-way) could contain suitable for Kincaid's lupine.

TABLE 3.7.5-1

Summary of Potential Suitable Kincaid's Lupine Habitat within the Right-of-Way (ROW) and Botanical Analysis Area

General Landowner	Suitable Habitat Status	Total Acres Surveyed [1] (2007-2017)	Acres Surveyed			Acres Not Surveyed [4]

[1] Acres provided in this column considers all surveys to-date (through 2017), including areas that have been subsequently rerouted or dropped (i.e., pipe yards) since surveys were initiated in 2007.
[2] Project includes: right-of-way, temporary extra work area, uncleared storage area, rock storage, pipe yards, aboveground facilities.
[3] Buffer (botanical analysis area) includes area within 30 meters (98 feet) of habitat removal and within 50 feet either side of an existing access road identified with possible road improvements.
[4] Areas not surveyed are either denied access or were not surveyed because of recent modification in Proposed Route that occurred after the flowering season, as well as areas outside of the targeted survey area (i.e., 30-meter analysis area vs. 50-foot targeted survey area on non-federal lands). "Not Habitat" was determined from adjacent survey parcel information, aerial photography, or "drive-by;" no surveys would be necessary and acres are not included.

Note: Surveys have continued in 2018 and the data are currently under review. Most area that remains to be surveyed occurs on private lands; surveys would continue as access becomes available.

Survey Results. Surveys for the Pipeline located three populations (approximately 1,330 plants) in 2007 (see table 3.7.5-2): two in western and one in eastern Douglas County (also see figures 3.7.5-1, 3.7.5-2, and 3.7.5-3). Two of the sites (MPs 57.84 through 57.92 and MP 59.60) are unique in Douglas County in that they occupy pasture / meadow habitat rather than forested habitats and may preserve high value genetic information and diversity.

TABLE 3.7.5-2

Summary of Kincaid's Lupine Locations

Milepost	Year Located	Number of Subpopulations	Number of Plants	Site Description
57.84-57.92	2007	7	199	Along centerline near MP 57.9; in the right-of-way and continuing south of the right-of-way at MP 57.85 - 57.90
59.6	2007	2	48	Outside of the construction zone and 30 meter analysis area.
96.48-96.9 [1]	2007	28	1,083	In the right-of-way and in access roads south of the right-of-way

[1] All plants in right-of-way obliterated from road construction and slash piles, only a few plants alongside access road observed (see discussion below).

Population at MPs 57.84-57.92. The first occupied site in western Douglas County was located along the right-of-way as proposed in 2007 between MPs 57.84 and 57.92 on private land (figure 3.7.5-1). This site was approximately 2.1 miles from a known site 1.5 miles northeast of MP 56.0, and approximately 1.6 miles southwest of the second site located during surveys in 2007 near MP 59.60. Approximately 199 plants were found at this site within seven subpopulations covering approximately 0.6 acre of area scattered within an approximately 4-acre area in pasture habitat. Subpopulations or patches ranged in size from 1 to 54 plants and are anywhere from 20 feet to 177 feet from each other (SBS 2008a). Plant counts were made by considering all stems in close proximity as one plant. Six of the seven patches were within 33 feet of each other and were assumed to be interconnected by below-ground stems; sub-population 7 was 150 to 190 feet from the other documented patches and was assumed to not be interconnected. Sub-populations were located approximately 2 feet south of the right-of-way (sub-population 7) and 3 to 438 feet north of the right-of-way (sub-populations 1 through 6).

This site was revisited in 2017 and the site appears to be stable or slightly increasing despite the removal of oaks along the fence line and continued grazing. One plant south of the right-of-way (sub-population 7) was not relocated in 2017 (SBS 2017a).

Population at MP 59.6. A second site was located on private land approximately 300 feet north of MP 59.60 and approximately 67 feet and 222 feet to the north and west of TEWA 59.30-N (figure 3.7.5-2). McNabb Creek Road, an identified existing access road (EAR 59.62) is approximately 40 and 85 feet to the south and west of this occurrence. Approximately 48 plants within two clumps or subpopulations (clonal groups) were documented covering approximately 0.5 acre scattered in a two-acre area on a flat grazed pasture (SBS 2008a). This site was also revisited in 2017. The two clumps of plants have migrated slightly farther from the Pipeline project, possibly as a response to grazing, but appear to be stable or slightly increasing in size (SBS 2017a).

Population at MPs 96.48-96.9. A third Kincaid's lupine site was found between MPs 96.5 and 96.9 and on proposed access roads south of MPs 96.7 to 96.9 during 2007 Pipeline survey efforts (figure 3.7.5-3); however, in late July 2015, the Stouts Creek fire burned through this population with a high intensity (all trees were killed and the ground scorched). The population was documented on private timberland two miles south of the South Umpqua River on a ridgeline east of Stouts Creek and was considered an important element in the recognized Stouts Creek-Callahan Ridge meta-population since it occurs in a central location between these populations thus forming an important genetic link. The plants were all located on loam soils in a young mid-seral mixed conifer and hardwood forest. Plants were documented within canopy gaps and, less regularly, under closed canopy (mostly under ponderosa pine trees) and in openings along four-wheel drive roads. Approximately 1,083 plants were located within 28 subpopulations or patches scattered within a 20-acre area. In all, plants occurred on an approximately 0.6-acre area (with approximately 29 percent cover). The 28 patches ranged in size from one plant to 258 plants in a 0.4-acre area and were documented within and adjacent to the Pipeline right-of-way and proposed access roads (see figure 3.7.5-3).

The area burned in 2015 was subsequently logged using ground-based equipment, roads were widened, and new roads built; large piles of slash from logging activities remain on site (SBS 2016). SBS (2016) revisited the site in June 2016 to determine the impact of the fire on the Kincaid's lupine population (MPs 96.5 through 96.9); all 28 sub-populations documented in 2007 were relocated and examined for re-sprouting lupine. Only two of the original 28 sites (subpopulations 8 and 16) had Kincaid's lupine growing (64 plants); subpopulation 8 is located 55 to 70 feet from proposed access road EAR 96.33 and 95 feet south of TEWA 96.25, and subpopulation 16 is located 20 feet from proposed access road EAR 96.33 and 395 feet south of TEWA 96.66-W. Proposed access road EAR 96.33 has been significantly widened since Stouts Creek fire. Many of the sites visited in 2016 suffered physical disturbance from heavy equipment, and several of the sites are under large slash piles. All sites that had been in or adjacent to proposed access roads were obliterated by the significantly widened roads. Eleven of the sites were relatively undisturbed, but no plants were present.

Although fire is a recommended method to manage habitat for Kincaid's lupine in prairie habitat, wildlfires have also been identified as a threat to Kincaid's lupine, especially if the fire destroys lupine plants before they senesce by mid-August and set seed for the next growing season (FWS 2006g). FWS (2008f) recommends prescribed burning in the late summer and early fall (September or October), after plants have set seed and senesced. Since the fire in 2015 occurred in late July/early August, it is possible plants in this population could have set seed. Lupine seedlings have the potential to return to this area, especially since legume seeds are known to be long-lived (Grigore and Tramer 1996; CPOP 2014), and Kincaid's lupine has evolved in a landscape with periodic wildfire, such that increased temperatures from the fire could have cracked the seed coat germinating previously dormant seeds (Grigore and Tramer 1996). PCGP will continue to monitor previous plant locations, as well as conduct full pre-construction surveys in the Pipeline project area between MPs 96.48 and 96.9.

Critical Habitat

The proposed action would not affect any of the PCEs identified because no critical habitat for Kincaid's lupine is present within the analysis area.

3.7.5.3 Effects of the Proposed Action

Direct and Indirect Effects

The report published on the biology of Kincaid's lupine (Wilson et al. 2003) indicates that Kincaid's lupine spreads extensively by physiologically-interdependent clones interspersed across large distances in the population, making it challenging to distinguish genetically distinct individual plants. Any estimates of number of individuals impacted by the proposed action are subject to broad margins of error. Because even broadly separated clones share resources through caudices, removal of stems from the occurrence may impact other connected clones, potentially increasing the number of plants impacted. There is no data to date regarding the short or long-term survivability of individuals when separated from the remainder of clone. Therefore, removing any individuals from small populations like those documented during survey efforts could decrease potential survival and decrease the ability for this species to readily colonize available habitats.

An important related concern is that these populations may consist of substantially fewer genetically distinct plants than estimated due to clonal growth. Kincaid's lupine depends on sexual reproduction to replace individual plants that may succumb to numerous threats to augment populations and to spread into suitable habitat. Such out-crossing plants require a large number of genetically distinct individuals as well as adequate pollinators to maintain genetic diversity and avoid negative effects of inbreeding depression, which may already be impacting these small remnant populations.

The three new populations of Kincaid's lupine identified during surveys in 2007 on private lands at MPs 57.84 through 57.92, 59.60, and 96.48 through 96.9 are too small to meet the minimum viable population size specified in the FWS recovery plan (either by estimated number of plants or by density within a coverage area). The newly found populations, however, may be contributing to other known meta-populations and recovery plan objectives, and removal of these plants may contribute negatively toward recovery of the species.

The population at MP 57.9 totals 0.6 acre within a four-acre area (15 percent cover) and the population at MP 59.6 is approximately 0.5 acre within a two-acre area (25 percent cover). Total cover at these population locations is high due to the vigor and age of the plants. These sites are approximately 2.1 to 2.7 miles from an extant site with plants of low vigor near Ten Mile, but far from other known sites, so are unlikely to be part of an eventual meta-population for meeting Recovery Plan goals (FWS 2008e). They do, however, contribute significantly to the "additional" population goals. These sites are unique for Douglas County in that they occupy Valley-Floor pasture/meadow habitats similar to Willamette Valley populations. As a result, plants identified during survey efforts may be preserving high value genetic information and diversity.

Prior to the 2015 Stouts Creek fire, the population near MP 95.6 was considered an important element in the recognized Stouts Creek-Callahan Ridge meta-population. It is approximately 2.5 miles east/northeast of the large known population cluster on BLM and Roseburg Timber lands at Stouts Creek, and approximately 2.7 miles west/northwest from the population on Forest Service and private land at Callahan Ridge, and approximately 3.7 miles from the population at Callahan Meadows. It occurs in a central location between these populations thus forming an important genetic link and increases the possibility of developing a successful South Umpqua "meta-population" to further achieve recovery goals. The population consisted of 28 patches within an area of 20 acres, occurring in transitory and natural openings in 45-year-old forest. The total cumulative area of the patches documented is approximately 0.57 acre (2.9 percent total cover), with the largest patch covering 0.09 acre. However, the combination of high intensity fire followed by physical disturbance to soils may preclude re-establishment of Kincaid's lupine at these sites.

Direct Impacts

During a previous iteration of the Pipeline project, PCGP met with several members of the Habitat Quality Subtask Group, to discuss impacts to documented plants and get recommendations on how to avoid or minimize impacts. In response to recommendations, PCGP rerouted the Pipeline near the population at MPs 57.84-57.92 south of six of the seven patches documented (see figure 3.7.5-1 and figure K-1 in appendix V2), completely avoiding all aboveground documented Kincaid's lupine patches. Subpopulation 7 (one plant, near MP 57.84) which was located south of the proposed Pipeline route is most likely not a part or clone of the other plants and should not be affected by dissecting below-ground stems. Additionally, surveys in 2017 did not relocate this plant. Therefore, no direct impacts to the subpopulations that are or were located at this site are expected.

No direct effects are expected at the second population near MP 59.60 documented north of TEWA 59.30-N, because the site is at least 67 feet from the Pipeline. Furthermore, direct impacts from use of the existing access road are also not expected (figure 3.7.5-2 and figure K-2 in appendix V2).

The third population between MPs 96.5 and 96.9 had an estimated 1,083 plants located within 28 subpopulations. As the proposed Pipeline route is located on a narrow ridgeline, there were no feasible routing alternatives to completely avoid this documented population. Therefore, to minimize impacts to this population, PCGP modified the construction right-of-way and TEWA 96.66-W to avoid impacts to 61 plants and partially avoid plants within a fourth subpopulation by narrowing the construction right-of-way (see figure 3.7.5-3). After modifications and prior to the 2015 Stouts Creek fire, approximately 35 plants (within three patches) were located within the proposed Pipeline project. When this population was revisited in 2016 after the Stouts Creek fire and subsequent salvage logging and road widening, no viable plants were located in the Pipeline right-of-way or within proposed access roads. Although no plants were relocated along the construction right-of-way in 2016, it is possible that construction of the Pipeline project and use of access roads could affect this population if plants resprout in this area. Because legume seeds are known to be long-lived, the lupine plants previously documented may have set seeds prior to the late July 2015 fire, and plants can be interconnected by underground stems up to 33 feet apart (FWS 2006g). Additional surveys would be conducted within this area prior to construction to determine the presence or absence of Kincaid's lupine plants. If plants or seedlings are located within the construction right-of-way, similar measures taken to avoid the plants previously within this milepost range would be applied to minimize impacts (see Attachment 1 within the *Federally-listed Plant Conservation Plan*, appendix V2).

Not all suitable habitats have been surveyed to date, indicating that additional Kincaid's lupine plants may be located within areas where direct impacts could occur. However, PCGP would implement the mitigation measures with respect to any identified populations that might be impacted by the Pipeline. The mitigation measures are described below in the "Conservation Measures" subsection and in the species-specific mitigation plan, appendix V2).

Indirect Impacts

Changes in the natural hydrology of a site can alter the annual duration of soil saturation, which in turn affects the species composition of the site. The potential for soil compaction along the construction right-of-way could occur from heavy equipment use and repeated vehicle traffic. Soil compaction can alter soil hydrologic conductivities, decreasing soil infiltration rates and available water contents, and increase runoff rates, or concentrate surface waters (such as along a settled trenchline). PCGP's ECRP (see appendix F describes the mitigation measures that would be implemented during restoration to alleviate potential soil compaction along the right-of-way to ensure revegetation success and to minimize any potential effects to Kincaid's lupine. Construction of the Pipeline in Kincaid's lupine meadow habitats could cause an increase in weedy grasses and forbs. In Kincaid's lupine forested habitat, a decrease in overstory canopy cover and subsequent shift to early seral vegetation associated with logging is expected with construction of the Pipeline. A reduction in canopy cover alone (i.e., without the ground disturbance associated with logging activities) could result in an improvement to forested Kincaid's lupine habitat. Kincaid's lupine is very sensitive to habitat loss, competition from nonnative plants, and elimination of historical disturbance regimes (and resulting competition from increased vegetation cover), all of which have contributed to the decline of Kincaid's lupine populations (FWS 2006g). Indirect impacts to documented patches of lupine are also possible from heavy dust created during construction activities and use of existing access roads and sub-surface disturbance to underground stems.

Cumulative Effects

Outside of the areas surveyed for this Project, it is unknown where Kincaid's lupine occurs on lands not under federal jurisdiction. Therefore, because the extent of this species on these non-federal lands is unknown, it is uncertain if there are reasonably foreseeable actions that might occur on these lands within areas currently occupied by this species. As the FWS's authority generally does not extend to listed plants on private or state lands,[17] all federally listed plants located on these lands must be considered at risk of adverse effects from potential developments. Other reasonably foreseeable projects on non-federal lands that could adversely affect this species include residential, commercial, and industrial development, as well as expanding agricultural areas.

PCGP has committed to implementing mitigation measures to address potential impacts to Kincaid's lupine regardless of land ownership.

Critical Habitat

Critical habitat has not been designated for Kincaid's lupine within the Project area; therefore, no designated critical habitat for this species would be impacted.

[17] The ESA does not protect plants outside federal land unless there is a federal nexus. Therefore, activities that occur on private or state lands that could affect listed plants but which do not have federal nexus are not required to consult with the FWS. Plants may not be removed from lands under federal jurisdiction, and activities with a federal nexus must consult with the FWS.

3.7.5.4 Conservation Measures

As described for the Applegate's milk-vetch, PCGP has developed a *Federally-listed Plant Conservation Plan* to address how avoidance, minimization, propagation, restoration, and other conservation measures would be applied to protect listed plant species, as well as how potential impacts on un-surveyed lands would be addressed. This plan also contains a Kincaid's Lupine Mitigation Plan that specifically addresses how mitigation would be implemented for the Kincaid's lupine (see Attachment 1 within the *Federally-listed Plant Conservation Plan*, appendix V2).

Because the removal of any Kincaid's lupine plants may hinder the recovery and eventual downlisting of the species, PCGP has avoided or minimized impacts to the populations of Kincaid's lupine that were located during survey efforts near MPs 57.84 to 57.92 and 96.5 to 96.9, as described in the Kincaid's mitigation plan (appendix V2). These measures included altering the proposed route, removing or minimizing proposed TEWAs, and/or minimizing the construction right-of-way (see figures 3.7.5-1, 3.7.5-2, and 3.7.5-3, as well as figures K-1, K-2, and K-3 in appendix V2). PCGP would conduct additional surveys within the Stouts Creek fire area (MP 96.5 to 96.9) to determine the presence or absence of Kincaid's lupine plants prior to ground-disturbing activities. If subsequent surveys continue to document the absence of these plants within the Pipeline right-of-way, PCGP would revert back to the previous disturbance footprint (i.e., remove neck-downs within the construction right-of-way and TEWAs that are called out in Figure K-3). If plants are located within the construction right-of-way, measures similar to those previously incorporated into the Pipeline project (see figure 3.7.5-3 and figure K-3 in appendix V2), would be implemented to minimize or avoid effects to observed plants, where necessary.

Persisting subpopulations at population MPs 96.5 to 96.9 identified along the existing access roads would be flagged by a qualified botanist prior to Pipeline activities in the area and PCGP's EIs would clearly fence the road edges adjacent to these subpopulations to minimize potential disturbance from road use and possible maintenance activities.

When access to the construction right-of-way is granted, surveys would be conducted in potential habitat (previously surveyed or unsurveyed). FWS would be notified of survey results. If plants are present, the avoidance/conservation measures included in the Kincaid's lupine mitigation plan would be implemented, where feasible. Measures of avoidance may include minor alignment reroutes, necking down the construction right-of-way in that area, excluding a portion of an identified temporary extra work area or pipe storage yard, or erecting a protective fence to avoid impacts to plants from construction debris (similar to actions taken or proposed at the previously identified Kincaid's lupine sites documented within the Pipeline project area).

If any Kincaid's lupine plants are observed within the construction area, seed collection would be completed prior to construction, after the plants have floweredand the seeds have developed and matured. Research has suggested that using pre-scarified seeds to establish Kincaid's lupine is more successful than salvaging and transplant efforts (Gisler 2004); direct seeding with pre-scarified seeds resulted in a 68 percent survival through the first growing season, versus only 5 percent of 150 seedlings sown. The collected seed would either be provided to a certified repository (i.e., The Berry Botanic Garden) or would be replanted within or adjacent to the construction right-of-way during restoration efforts on suitable BLM lands where future protection can be managed or on private lands where a conservation easement has been acquired. If planting is to occur on the construction right-of-way, it would occur outside the 30-foot maintained easement.

Additional mitigation measures for impacts to individual Kincaid's lupine plants would include application of measures included in the Integrated Pest Management Plan (appendix N to the POD) to control existing noxious weeds and prevent new infestations within and adjacent to occupied and potential habitats. Competition with invasive species (e.g., Himalayan blackberry, oxeye daisy, grasses, Scotch broom) have been the biggest threat to maintaining or reestablishing Kincaid's lupine in some locations (Thorpe and Massatti 2008; Thorpe et al. 2009); therefore, control of these invasive species could have a beneficial impact on Kincaid's lupine. Other measures could include planting native forbs and shrubs adjacent to Kincaid's lupine populations to encourage a variety of pollinating insects. Controlling canopy cover in occupied or potential wood habitats could also stimulate growth of existing clones if shading is judged to be a limiting factor.

It is possible that clones of Kincaid's lupine could become established within the construction right-of-way where rerouted near MPs 57.84 to 57.92, or could resprout within the Stouts Creek Fire area near MPs 96.5 to 96.9. PCGP has agreed to monitor revegetation success in the areas of the restored Kincaid's lupine populations (between MPs 57.84 to 57.92 and MPs 96.5 to 96.9) annually for five years after completion of construction. Monitoring would include inspection between those mileposts for any new growths of Kincaid's lupine. If any are found, only mowing to comply with DOT requirements would be conducted. The five-year monitoring period is longer than FERC's three-year monitoring period requirement for sensitive areas such as wetlands (see section VI.D.3. of FERC's *Procedures*).

3.7.5.5 Determination of Effects

Species

The Project **may affect** Kincaid's lupine because:

- suitable habitat is present within the analysis area; and
- individual plants have been located within the analysis area during survey efforts.

The Project is l**ikely to adversely affect** Kincaid's lupine because:

- surface disturbance and excavation would occur within potentially suitable habitats, which may contain un-identified plants, or may be able to support this species in the near future;
- indirect impacts are expected to documented or suspected plants outside of the construction right-of-way (within 30 meters) and along proposed access roads;
- trenching activities associated with the proposed Pipeline could impact below-ground stems and the expected impact to extant plants is unknown; and
- potential suitable habitat has not been surveyed due to landowner access denial.

Critical Habitat

A **no effect** determination is warranted for Kincaid's lupine because:

- the Pipeline does not occur within designated Kincaid's lupine critical habitat.

3.7.6 Rough Popcornflower

The rough popcornflower (*Plagiobothrys hirtus*) is an annual herb in the borage (Boraginaecae) family. It is found in wetlands in the Umpqua River valley in Douglas County, Oregon (FWS 2000d).

3.7.6.1 Species Account and Critical Habitat

Status

The rough popcornflower was listed as endangered on January 25, 2000 (FWS 2000d). There has been no critical habitat designated for this species.

Threats

FWS listed the rough popcornflower as threatened based on the destruction, modification, or curtailment of its wetland habitat and range. At that time, the species was limited to 17 small isolated habitat patches. Areas supporting the rough popcornflower were threatened by hydrological alterations (including ditching and wetland fill), livestock grazing, agricultural land conversion, non-native vegetation invasion, forest succession and canopy cover, as well as residential and commercial development.

Predation and other natural or manmade factors are also threats identified in the endangered status ruling. These factors include herbicide and pesticide use, chemical spills and runoff from roads, roadside maintenance, habitat vandalism, and grazing. Overgrazing likely contributed to declining numbers throughout its historical range, with livestock grazing in spring and summer months causing the most damage. When flowers and seed heads are grazed, the reproductive output for the year is destroyed; however, FWS noted in its listing decision that grazing in the fall, during the plant's dormant stage, can be a benefit to the species by reducing the growth of weedy competitors (FWS 2000d). The small, isolated populations also make the species vulnerable to disease outbreaks, weak genetic viability, adverse pollinator activity, and random environmental events.

Since the publication of the final rule for rough popcornflower, the potential for further development in the plant's habitat remains the most urgent threat. Habitat destruction and fragmentation from residential, commercial, and agricultural development continues as the area around Sutherlin, Oregon expands. Competitive exclusion by other wetland vegetation is another major threat to the plant. Other ongoing threats include forest succession, overgrazing by livestock, chemical spills and fire along roadsides, herbicide use, wetland infill, and the intentional destruction of suitable habitat and plants (FWS 2003f).

Species Recovery

A recovery plan was developed in 2003 (FWS 2003f), which created three recovery units to ensure that the rough popcornflower was conserved throughout its range in the North Umpqua system. The recovery plan identified that nine reserves, each containing a minimum of 5,000 plants, should be distributed across the three recovery units of Calapooya Creek, Sutherlin Creek, and Yoncalla Creek (FWS 2003f). The objective of the recovery plan is to reduce threats and increase population viability until the rough popcornflower can be downlisted. The recommended steps are as follows:

- Conserve and manage a minimum of nine reserves within three recovery units.
- Practice ex-situ conservation.
- Research factors that threaten the recovery of the species.
- Provide outreach services for owners of reserve populations and the general public.

All the recovery units identified in the recovery plan occur more than 17.5 miles north of the Pipeline right-of-way and more than 4 miles north of the nearest proposed pipe storage yard.

Life History, Habitat Requirements, and Distribution

The rough popcornflower is currently found in seasonal wet meadows or wet prairies in poorly drained clay or silty clay loam soils at elevations ranging from 100 to 900 feet. Deep, poorly drained soils provide a high-to-surface-level water table from November to May, when rough popcornflowers' seedlings germinate and overwinter as submerged rosettes. In these areas, the rough popcornflower is often observed in the deeper sections of shallow meadow pools that lack significant shade and is associated with typical marshland sedge and grasses (FWS 2003f).

Rough popcornflower generally blooms from June through July. Rough popcornflower grows in scattered groups and reproduces largely by insect-aided cross-pollination and partially by self-pollination (FWS 2008g). The herbaceous plant occurs near the towns of Sutherlin and Yoncalla, mostly on private lands in the Umpqua River drainage (FWS 2003f).

Population Status

As of 2010, there were 14 extant populations of rough popcornflower, distributed from Yoncalla Creek near Rice Hill, south to Sutherlin Creek near Wilbur, of which five populations have been introduced (FWS 2010g). Six populations are considered protected and have a documented occupancy of at least 5,000 plants (FWS 2010g). Populations range from 75 plants to more than 35,000 plants (FWS 2010g).

Critical Habitat

Critical habitat has not been designated for the rough popcornflower.

3.7.6.2 Environmental Baseline

Analysis Area

The botanical analysis area extends to 30 meters (98 feet) each side of the Pipeline project (construction right-of-way, TEWAs, UCSAs, rock source and disposal sites, and proposed storage yards) on lands that have potential habitat for listed plant species. This area generally corresponds to the extent of the area surveyed for sensitive and listed plant species during surveys conducted between 2007 and 2017 (at least 100 feet from habitat removal on federal lands and at least 50 feet from habitat removal on non-federal, private lands), and correlates to a distance that indirect effects to plants would be expected.

Species Presence

This species has only been documented in northern Douglas County. The nearest occupied habitats to the Pipeline are along Sutherlin Creek, which is within the Lower North Umpqua River watershed (HUC 171003011), and extend from inside the city of Sutherlin to the south approximately four miles. ORBIC (2017b) reported this plant within multiple sub-populations approximately 1.7 miles north of the proposed Winchester pipe storage yard where 62,765 plants were documented in 2016. The closest rough popcornflower occurrence to the Pipeline right-of-way is approximately 17.5 miles north of MP 68 (ORBIC 2017c).

Project-Specific Rough Popcornflower Survey

Habitat Surveyed. Prior to beginning field surveys in 2007 for the Pipeline, botanists with SBS conducted a habitat review to identify potential habitat and delineate survey areas for rough popcornflower within the botanical analysis area from MPs 51.7 through 67, including existing roads identified for access to the construction right-of-way. Aerial photographs and knowledge of regional landscape and biological features (soils, geology, topography, elevation, target species habitat, and plant community habitat) were used to determine potential habitat for rough popcornflower. The same methods were used to determine potential suitable habitat coinciding with new realignments of the project corridor since 2007.

Overall, 12.89 acres have been surveyed by PCGP from 2007 through 2017 for rough popcornflower within the vicinity of the proposed Pipeline, including previously proposed routes and project components, alternate routes considered, and along access roads that are no longer considered for the Pipeline project. Surveys have continued in 2018 and the data are currently under review. Within the 30-meter botanical analysis area of the Proposed Action where survey permission was granted, approximately 2.79 acres (1.07 acres within the Pipeline project) had been identified as suitable habitat and 6.43 acres were determined not to be suitable habitat for the rough popcornflower (see table 3.7.6-1). Habitat found to be "suitable" in the surveys included areas with some of the characteristics detailed in the Life History, Habitat Requirements, and Distribution section above. Table 3.7.6-1 provides a summary of potential suitable rough popcornflower habitat and survey status within the botanical analysis area.

TABLE 3.7.6-1

Summary of Potential Suitable Rough Popcornflower within the Right-of-Way and Botanical Analysis Area

General Landowner	Suitable Habitat Status	Total Acres Surveyed [1] (2007-2017)	Acres Surveyed			Acres Not Surveyed [4]		
			Project [2]	Buffer [3]	Total	Project [2]	Buffer [3]	Total

[1] Acres provided in this column considers all surveys to-date (through 2017), including areas that have been subsequently rerouted or dropped (i.e., pipe yards) since surveys were initiated in 2007.
[2] Project includes: right-of-way, temporary extra work areae, uncleared storage area, rock storage, pipe yards, aboveground facilities.
[3] Buffer (botanical analysis area) includes area within 30 meters (98 feet) of habitat removal and within 50 feet either side of an existing access road identified with possible road improvements.
[4] Areas not surveyed are either denied access or were not surveyed because of recent modification in Proposed Route that occurred after the flowering season, as well as areas outside of the targeted survey area (i.e., 30-meter analysis area vs. 50-foot targeted survey area on non-federal lands). "Not Habitat" was determined from adjacent survey parcel information, aerial photography, or "drive-by;" no surveys would be necessary and acres are not included.

Note: Surveys have continued in 2018 and the data are currently under review. Most area that remains to be surveyed occur within Winchester pipe storage yard; surveys would continue as access becomes available.

Access to approximately 99.83 acres (82.63 acres within the Pipeline project) of potentially suitable habitat for this species has not been granted within the botanical analysis area, of which the majority of acres (93.16 acres) are associated with the proposed Winchester pipe storage yard and buffer. PCGP would continue to survey habitat where permission is granted. Where survey access has been denied, PCGP would conduct surveys in suitable habitat within the Pipeline project prior to construction.

Survey Results. No rough popcornflower individuals were located during surveys conducted during Pipeline survey efforts.

Critical Habitat

Critical habitat has not been designated for this species.

3.7.6.3 Effects of the Proposed Action

Direct and Indirect Effects

Surveys conducted within potential suitable rough popcornflower habitat along the Pipeline right-of-way did not locate any plants. Additional habitat has been identified in the vicinity of the Pipeline right-of-way where surveys have not been permitted; however, given that the nearest known occurrence of rough popcornflower is over 17 miles north of the Pipeline route, it is unlikely that rough popcornflower plants would be documented along the right-of-way. Potential wetland habitat for the species may be present at the proposed Winchester pipe storage yard, which is located 1.7 miles south of documented occurrences. If PCGP determines that it would use this pipe storage yard during construction of the Pipeline, surveys for rough popcorn flower would be conducted. If plants are documented, PCGP would either not use the pipe storage yard or, if the yard is necessary, not use that portion of the yard where plants are documented. However, due to the current use of this pipe yard and adjacent highway, any plants found adjacent to these areas would likely already be experiencing indirect impacts.

Based on the information presented above, direct impacts to this species are unlikely to occur (i.e., the project is unlikely to occur in areas occupied by rough popcornflower). Indirect impacts could, however, occur if this plant is located within or adjacent to Winchester pipe storage yard or the unsurveyed portion of the Pipeline through dust generated via use of the area, changes in runoff and hydrology, or through the spread/establishment of weeds.

Cumulative Effects

Outside of the areas surveyed for this Project, it is unknown where rough popcornflower occurs on lands not under federal jurisdiction. Therefore, because the extent of this species on these non-federal lands is unknown, it is uncertain if there are reasonably foreseeable actions that might occur on these lands within areas currently occupied by this species. As the FWS's authority generally does not extend to listed plants on private or state lands,[18] all federally listed plants located on these lands must be considered at risk of adverse effects from potential developments. Other reasonably foreseeable projects on non-federal lands that could adversely affect this species include residential, commercial, and industrial development, as well as expanding agricultural areas.

PCGP has committed to implementing appropriate mitigation measures for any listed plants, regardless of land ownership.

3.7.6.4 Conservation Measures

It is possible that rough popcornflower plants could be present in Winchester pipe storage yard, considering distance to recently documented plants along Highway 99 (ORBIC 2017c) and the potential for suitable wetland habitat on the eastern edge of the proposed yard. If plants are documented in the Winchester pipe storage yard, PCGP would either not use the pipe storage yard or, if the yard is necessary, not use that portion of the yard where plants are documented. Additionally, mitigation measures included in the *Federally-Listed Plant Conservation Plan* (appendix V2) would further minimize impacts to rough popcornflower plants if documented during preconstruction surveys.

3.7.6.5 Determination of Effects

Species

The Project **may affect** rough popcornflower because:

- populations occur in the vicinity of one proposed pipe storage yard; and
- potential suitable habitat might be present within the 30-meter botanical analysis area.

The Project is **not likely to adversely affect** rough popcornflower because:

- surveys for the Pipeline project have not documented rough popcornflower, where survey permission has been granted;

[18] The ESA does not protect plants outside federal land unless there is a federal nexus. Therefore, activities that occur on private or state lands that could affect listed plants but which do not have federal nexus are not required to consult with the FWS. Plants may not be removed from lands under federal jurisdiction, and activities with a federal nexus must consult with the FWS.

- surveys in potentially suitable habitat identified within Winchester pipe storage yard or within potential habitat identified within the botanical analysis area along the right-of-way would occur prior to ground disturbing activities; if plants are identified, conservation measures developed to avoid or minimize impacts to future plants would be applied;
- consultation with the FWS would be reinitiated if this species is found to be present in the area and impacts cannot be avoided.

Critical Habitat

Critical habitat has not been designated for rough popcornflower.

4.0 ESSENTIAL FISH HABITAT

The Sustainable Fisheries Act of 1996 amended the MSA and requires federal agencies, in part, to consult with NMFS about activities that may adversely affect EFH (NMFS 1997a). The MSA established guidelines for Regional Fishery Management Councils to identify and describe EFH in FMPs to responsibly manage exploited fish and invertebrate species in federal waters. The PFMC has developed four FMPs that address EFH for managed species in the project area (PFMC 2004, 1998, and 1999).

The MSA describes EFH as those waters and substrate necessary to fish for spawning, breeding, feeding, or growth to maturity (NMFS 1997a). The MSA provides these additional definitions:

- "Waters" include aquatic areas and their associated physical, chemical, and biological properties that are used by fish, and may include areas historically used by fish where appropriate;
- "Substrate" includes sediment, hard bottom, structures underlying the waters, and associated biological communities;
- "Necessary" means the habitat required to support a sustainable fishery and the managed species contribution to a healthy ecosystem; and
- "Spawning, breeding, feeding, or growth to maturity" covers the full life cycle of a species.

One purpose of this EFH assessment is to determine whether, and to what degree, Project actions would adversely affect any of the EFH within the analysis areas. NMFS (2015d) defines a project action that will adversely affect EFH as:

> *any impact that reduces quality and/or quantity of EFH. This includes direct or indirect physical, chemical, or biological alterations of the waters or substrate and loss of, or injury to species and their habitat, and other ecosystem components, or reduction of the quality and/or quantity of EFH. Adverse effects may result from actions occurring within EFH or outside of EFH.*

There are three general analysis areas in which Project effects to EFH are assessed:

- marine: the marine waters extending from the mainland marine coastline (excluding Coos Bay), out to 15 nmi that may be affected by LNG carriers or other project actions;
- estuarine: the waters of Coos Bay; and
- riverine: freshwater areas that may be affected by project actions in fifth-field watersheds currently containing EFH species.

The Pacific Fishery Management Council (PFMC) has developed four Fishery Management Plans (FMPs) that address Essential Fish Habitat (EFH) for managed species in the Project action area. There are four federal FMPs and associated EFH that coincide with these analysis areas. They include highly migratory species, coastal pelagic species, groundfish, and Pacific Coast salmon. Within these analysis areas, EFH has been designated for two salmonid species, five pelagic species, 70 groundfish species, and over a dozen highly migratory species as described below.

EFH has been defined by the PFMC out to the limits of the United States Exclusive Economic Zone (EEZ). Marine traffic associated with construction and operation of the LNG Terminal may affect EFH beyond the marine analysis area (that is, beyond the limits of the OCS out to the limits of the EEZ). For example, vessel traffic would generate localized noise, and impacts on water quality may occur due to discharge of ballast water, intake and discharge of cooling water, or accidental spills of pollutants at sea. However, Coos Bay and the waters offshore out to the limits of the EEZ currently provide deepwater access for maritime commerce, and support high levels of deep draft vessel traffic. Any impacts due to the incremental increase in marine vessel traffic during construction and operation of the Project would not have a significant adverse effect on EFH outside of the marine analysis area of the Project action area. As a result, the analysis of potential adverse effects to EFH coincides with the Project action area under the ESA, and the EFH Assessment has been incorporated into the APDBA. 50 CFR § 600.920(e)(3).

See section 1.0 of this BA for a description of the Project, including a description of the proposed facilities (section 1.2) and proposed conservation measures (section 1.3). Section 3.5 analyzes the effects of the Project on ESA listed fish species and supplies most of the analysis provided in this EFH as it addresses effects to fish species and their habitat in all three analysis areas defined above.

The following discussion focuses on the potential effects to habitats for groups of species, not individual species. Table 4.0.0-1 provides a summary of the EFH habitat description, Project actions that may contribute to adverse effects to EFH, and overall determination of adverse effects for each EFH group.

TABLE 4.0.0-1

Potential Impacts to EFH due to Construction and Operations

EFH	Description of EFH a/	Potential Impacts	Determination of Effects
Highly Migratory Species	EFH is defined by temperature ranges, salinity, oxygen levels, currents, shelf edges, and sea mounts. Based on species characteristics, the closest EFH would be beyond the 40-fathom depth off of Coos Bay. b/	• Accidental spills of hazardous substances	Minimal adverse effects or negligible effects to highly migratory species EFH
Coastal Pelagic Species	All marine and estuarine waters from the coast to the limits of the EEZ and above the thermocline where sea surface temperatures range between 50°F and 79°F	• Accidental spills of hazardous substances • Dredging of 62.7 acres of estuarine habitat in Coos Bay • Installation of two HDDs across Coos Bay • • Potential impingement or entrainment of small fish, food and larval organisms from dredging and LNG carrier cooling water intake	Habitat effects minimal; Significant adverse effects to coastal pelagic species unlikely (northern anchovy, Pacific sardine) EFH
Groundfish	All waters from the extent of the high tide line (and parts of estuaries) to	• Accidental spills of hazardous substances	Habitat effects minimal; Significant adverse

	offshore to the 3,500-meter (1,914-fathom) depth.	• Dredging of 62.7 acres of estuarine habitat in Coos Bay • Short-term water quality degradation should a low-probability inadvertent return occur during installation of two HDDs across Coos Bay • Potential impingement or entrainment of small fish, food, and larval organisms •	effects to multiple groundfish species unlikely (e.g., rockfish, English sole, starry flounder) EFH
Pacific Coast Salmon	All streams, lakes, ponds, wetlands, and other waterbodies currently and historically accessible to salmon. Estuaries and marine areas extending to the EEZ and beyond.	• Accidental spills of hazardous substances • Dredging of 62.7 acres of estuarine habitat in Coos Bay • Installation of two HDDs across Coos Bay • Periodic channel dredging and disposal • Short-term increase in noise associated with land based pile driving at the MOF and in-water pile driving at various temporary construction activities • Potential impingement or entrainment of small fish, food and larval organisms • Fish salvage during stream crossings • Short-term loss of nearshore cover, prey species, and long-term loss of sources of large woody debris recruitment from riparian vegetation removal • Elevated suspended sediment at pipeline stream crossings • Diverted open-cut across South Umpqua River, installation of HDD across Coos River and Rogue River	Isolated and localised adverse effects to Pacific coastal salmon species (coho and Chinook salmon) EFH

a/ PFMC (2006; updated version July 24, 2006)
b/ PFMC (2007)

4.1 ESSENTIAL FISH HABITAT DEFINITION

As noted, there are four FMP fish habitat groups. The characteristics of each of the habitats and associated species relative to Project analysis areas are summarized below.

4.1.1 Highly Migratory Species

Highly migratory species are species that only occur within the marine analysis area since they migrate considerable distances across oceans to feed and reproduce. Highly migratory species defined by the PFMC include tunas (five species), sharks (five species), billfish/swordfish (two species), and the dorado (also called dolphinfish or mahi-mahi). However, highly migratory species and their various life stages are not uniformly distributed within the marine analysis area. Species' life cycles included in table 4.1.1-1 have been separated by their distributions in the EEZ north of 37°N latitude (north of Monterey Bay, California). The earliest life stages for most highly migratory species on the U.S. West Coast occur south of Monterey Bay, outside the marine analysis area. Based on their distribution in mostly warmer waters and usually well outside the coastal area habitat that is typical of the marine area near Coos Bay, none of these fish are likely to be present in the immediate marine waters near the entrance to Coos Bay.

TABLE 4.1.1-1

Highly Migratory Fish Species Managed by the Pacific Fishery Management Council for which Essential Fish Habitat Has Been Identified and May Occur Within the Proposed Action Marine Analysis Area

		Distribution within the EEZ Analysis Area North of 37°N Latitude				
Common Name/ ***Scientific Name***	**Life Cycle and Habitat Associations a/**	**Eggs**	**Larvae**	**Neonate-Early Juvenile b/**	**Late Juvenile - Sub-adults b/**	**Adult**
Common thresher shark *Alopias vulpinus*	Epipelagic, neritic, and oceanic waters off beaches, in shallow bays, open coast bays and offshore, in near surface waters. Feeds primarily on northern anchovy, Pacific hake, Pacific mackerel, and sardine.					X
Bigeye thresher shark *Alopias superciliosus*	Coastal and oceanic waters in epi- and mesopelagic zones. Little known of diet; presumably feeds on pelagic fish and squids.					X
Blue shark *Prionace glauca*	Epipelagic and oceanic waters. Feeds on northern anchovy, Pacific hake, squid, spiny dogfish, herring, and flatfish.			X	X	X
Shortfin mako shark *Isurus oxyrinchus*	Oceanic and epipelagic waters. Reportedly feed on mackerel, sardine, bonito, anchovy, tuna, other sharks, swordfish, and squid.			X	X	X
Albacore *Thunnus alalunga*	Oceanic, epipelagic waters. Feed opportunistically. Younger fish may aggregate in vicinity of upwelling fronts to feed.			X		X
Northern bluefin tuna *Thunnus thynnus*	Juvenile-oceanic, epipelagic waters. Major part of diet is northern anchovy.			X		
Skipjack tuna *Katsuwonus pelamis*	Adult-oceanic, epipelagic waters. Major part of diet are pelagic red crab and northern anchovy.					X
Broadbill swordfish *Xiphias gladius*	Oceanic, epipelagic, and mesopelagic waters. Food species not documented.			X		X

a/ PFMC 2007.
b/ All juvenile life stages are combined for species other than sharks.

4.1.2 Coastal Pelagic Species

Coastal pelagic species include four fin fish—northern anchovy, Pacific sardine, Pacific (chub) mackerel, and jack mackerel—and the invertebrate market squid. Coastal pelagic species occur from the ocean surface to depths of 1,000 meters (547 fathoms within the marine analysis area, but the distributions of several species tend to be in relatively shallow water closer to shore, including the estuarine analysis area). These species are not associated with the seafloor or bottom substrates. EFH for coastal pelagic species also includes portions of the water column where sea surface temperatures range between 50°F (near the United States/Mexico maritime boundary) and 79°F (seasonally and annually variable) (PFMC 2006).

All life stages for each of the coastal pelagic species are expected to occur within the marine analysis area, and the adults of most species are expected within the estuarine analysis area (table 4.1.2-1). Northern anchovies are the only coastal pelagic species for which all life stages are likely to utilize the estuarine analysis area (table 4.1.2-1), although some life stages of Pacific sardine and Pacific mackerel may be present. In Coos Bay, these are not resident species, but are primarily present in the summer months. During the summer, the estuary may be utilized as a forage area for juveniles and adults, and as a nursery area for larvae and juveniles for some of the species.

Within the Coos Bay estuary, northern anchovies are expected to be transient users of eelgrass (Phillips 1984). Eelgrass provides indirect benefits to these species by contributing to productivity in the estuary, and eelgrass drift may provide cover for coastal pelagic species (Nightingale and Simenstad 2001).

TABLE 4.1.2-1

Coastal Pelagic Fish Species Managed by the Pacific Fishery Management Council for which Essential Fish Habitat Has Been Identified and May Occur within the Proposed Action Estuarine Analysis Area and Marine Analysis Area

		Distribution within Estuarine Analysis Area				**Distribution within Marine Analysis Area**			
Common Name ***Scientific Name***	**Life Cycle and Habitat Associations a/**	**Eggs**	**Larvae**	**Juvenile**	**Adult**	**Eggs**	**Larvae**	**Juvenile**	**Adult**
Pacific sardine *Sardinops sagax*	Pelagic commercially harvested schooling fish that inhabits coastal subtropical and temperate waters. Occurs in estuaries, but more commonly near shore and offshore. Highly mobile, moving seasonally along the coast. More abundant in Oregon during the summer and warm water years. Spawning occurs year-round (spatially and seasonally dependent on temperature) in loosely aggregated schools in the upper 50 yards of the water column, generally 30-90 miles offshore. Major prey species for commercially valuable and endangered fish species.			?	X	X	X	X	X
Northern anchovy *Engraulis mordax*	Often in schools near the surface. Spawning occurs every month, especially in late winter and early spring (February–April). Overwinter in mixed layer temperatures. Nearshore habitats support most of the juvenile population. Eat phytoplankton or zooplankton by either filter-feeding or biting. Considered a valuable source of food for endangered fish and bird species.	X	X	X	X	X	X	X	X
Pacific (chub) mackerel *Scomber japonicus*	Pelagic for all life stages. Adults commonly found in shallow banks with increased abundance from July to November. Spawning peaks April through July in California.			?	?	X	X	X	X
Jack Mackerel *Trachurus symmetricus*	Pelagic schooling fish that range widely. Diet on large zooplankton, juvenile squid, and anchovy. They are more available on offshore banks in late spring, summer and early fall than during the remainder of the year. Much of their range lies outside the 200 mile EEZ.				X	X	X	X	X
Market Squid *Loligo opalescens*	Prefer oceanic salinities and rarely found in bays, estuaries, or near river mouths. Spawning occurs year-round. They are important as forage foods for many species.		X	X	X	X	X	X	X

a/ PFMC 2007

4.1.3 Groundfish Species

There are over 80 species of groundfish, most of which live at or near the ocean bottom, that are managed under the Pacific Coast Groundfish FMP (PFMC 2008). Many groundfish species occur within the marine and estuarine analysis areas. This FMP includes EFH within the waters and substrates at "depths less than or equal to 3,500 m (1,914 fm) to mean higher high water level (MHHW) or the upriver extent of saltwater intrusion, defined as upstream and landward to where ocean-derived salts measure less than 0.5 ppt during the period of average annual low flow" (PFMC 2005). Species and their likely life stage distributions in the Project analysis areas are summarized in table 4.1.3-1 (at the end of this section). This distribution is based on mapped habitat suitability probabilities for spatial occurrences by different life stages (Appendix B-4 in PFMC 2006). Although many groundfish species have the potential to be in the estuary based on the PFMC habitat maps, only 19 species are considered to be more than "unlikely" in the estuarine analysis area. Based on sampling within Coos Bay estuary, at least 16 groundfish species are known to be present (see JCEP's Resource Report 3, appendix E.3; Wagoner et al. 1990).

Most groundfish species are not residents of Coos Bay but utilize the bay primarily in the spring and summer months. During spring and summer, the estuary may be utilized as a forage area for juveniles and adults, and as a nursery area for larvae and juveniles. For example, starry flounder spawn near river mouths and sloughs. Juvenile starry flounder are found exclusively in estuaries. Sampling in upper Coos Bay from 1979 to 1990 showed that young-of-the-year flounder are present at least in the spring and summer months (Wagoner et al. 1990). Flounder and sole are found in sandy or muddy substrate, and juveniles are found in shallow water near rivers and in estuaries in eelgrass beds. Adults generally are found in deeper waters in the winter and migrate to shallower water in the spring. Juvenile English sole depend heavily on intertidal areas, estuaries, and shallow nearshore waters for food and shelter.

The black rockfish is the only member of the rockfish family that is consistently caught in the Coos Bay recreational fishery. Other species caught include copper, blue, grass, and canary rockfish, as well as bocaccio (Wagoner et al. 1990). Rockfish occur in the lower areas of Coos Bay, mainly during the late spring and summer months (Wagoner et al. 1990). Black rockfish are not known to spawn in estuaries. Rockfish recruit to seagrass beds in shallow, soft bottom embayments (Love et al. 1991). Johnson et al. (2003) reported that juveniles of many commercially important species utilize eelgrass habitat in Southeastern Alaska. Rockfish juveniles settle into shallow, vegetated habitats for rearing. Vegetated habitats (eelgrass and kelp) provide refuge from predators and access to prey. Juvenile rockfish may also be closely associated with seagrass drift for both feeding and refugia while they move between pelagic and near shore habitat (Nightingale and Simenstad 2001).

Rockfish have not been observed by ODFW while seining in or near the immediate Project slip area, indicating that this area is not likely utilized by rockfish (ODFW 2006a). Black rockfish and cabezon, however, were the most abundant juvenile rockfish species captured elsewhere within Coos Bay (near the entrance), between June 2003 and December 2005 (Schlosser and Bloeser 2006). Trap sites were located in eelgrass beds, along dock pilings, and in sandy bottom habitat near the entrance to Coos Bay. Juvenile chillipepper, copper, grass, yellowtail, and kelp greenling were also captured near the Coos Bay entrance.

Lingcod begin life in near-surface marine waters and estuarine areas. Juvenile lingcod primarily use estuaries, entering to feed, while adults are usually found in marine waters that are 100 to 150 meters deep. Lingcod lay eggs in rocky, marine subtidal areas. Larvae are found in the near-surface marine waters and estuarine areas. In this life stage, lingcod feed primarily on copepods, eggs, and other crustaceans. As lingcod mature, they are commonly found in shallow, inter-tidal areas of bays near algae and seagrass beds.

TABLE 4.1.3-1

Groundfish Species Managed by the Pacific Fishery Management Council for which Essential Fish Habitat Has Been Identified and May Occur Within the Proposed Action Estuarine Analysis Area and Marine Analysis Area

Common Name Scientific Name	Life Cycle and Habitat Associations a/	Distribution within Estuarine Analysis Area b/				Distribution within EEZ Analysis Area b/			
		Eggs c/	Larvae c/	Juvenile c/	Adult c/	Eggs c/	Larvae c/	Juvenile c/	Adult c/
Soupfin shark *Galeorhinus galeus*	Coastal-pelagic species associated with the bottom, inhabiting bays, muddy shallows and offshore up to 225 fathoms (fm). Adult males occur in deeper waters and females usually at less than 30 fm. From dense shoals, migrating north in the summer and south in the winter. Mating occurs in the spring.			L	M			H	H
Spiny dogfish *Squalus acanthias*	An inner shelf-mesobenthal species with a depth range of 0 to 677 fm. Common in inland seas and shallow bays. Seasonal migrations occur within preferred temperature range.			L	H			H	H
Leopard shark *Triakis semifasciata*	Inhabits enclosed muddy bays, flat sandy areas, mud flats, sandy and muddy bottoms strewn with rock near reefs and kelp beds. Common in littoral waters and around jetties and piers. Pupping and feeding/rearing grounds in estuaries and shallow coast waters. Found at depths up to 50 fm, common at 0 to 2 fm.			H	H			H	H
Big skate *Raja binoculata*	Inhabits inner and outer shelf areas, particularly on soft bottom sediments. Either associated with silty sediment, or with sediment consisting of a mixture of mud, sand, gravel, and cobble. Found at depths up to 55 fm.	U		U	U	H		H	H
California skate *Raja inornata*	Usually occur in habitats with muddy bottoms. Juveniles are associated with soft bottom sediments. Common in inshore waters and shallow bays; sometimes in deep water.	H		U	H	H		H	H
Longnose skate *Raja rhina*	Occurs on the bottom inner and outer shelf areas, usually less than about 175 fathoms deep. Juveniles and adults are associated with soft bottom sediments with combinations of mud and cobble near high relief structures.	L		U	U	H		H	H
Pacific cod *Gadus macrocephalus*	Adults and juveniles prefer mud, sand, and clay. Usually found near bottom, with a wide depth range of 7 to 300 fm. Spawning occurs from the late fall to early spring. Larvae and small juveniles are pelagic, large juveniles and adults are parademersal.	L	U	U	U	H	H	M	L
Pacific grenadier (rattail) *Coryphaenoides acrolepis*	Commercial species that inhabits the continental slope. Highest densities occur on the sandy bottoms of abyssal plains. Migrations have not been documented, but larger fish are found in deeper water. Larvae are pelagic.	H	H	U	U	H	H	L	H
Pacific whiting (hake) *Merluccius productus*	Inhabits euhaline waters of the continental shelf. Juveniles reside in shallow coastal waters, bays, and inland seas and move deeper as they get older. Highly migratory. Spawns from December through March, perhaps more than once per season.	U		U	L	H		U	H
Spotted ratfish *Hydrolagus colliei*	Found near the bottom, from close inshore to about 500 fm. Abundant in cold waters at moderate depths. Feed on mollusks, crustaceans and fish; also echinoderms and worms. Fishers are reputed to fear the jaws of the ratfish more than they do the dorsal spine.	U		U	U	H		H	H

Common Name **Scientific Name**	**Life Cycle and Habitat Associations a/**	**Eggs c/**	**Larvae c/**	**Juvenile c/**	**Adult c/**	**Eggs c/**	**Larvae c/**	**Juvenile c/**	**Adult c/**
Rougheye rockfish *Sebastes aleutianus*	Usually found on the bottom in deep, offshore waters with soft substrata, frequenting boulders and at slopes greater than 20 degrees. Depths range from 14 to 478 fm.			U	U			H	L
Pacific Ocean Perch *Sebastes alutus*	This commercially important schooling fish is abundant offshore, often found along submarine canyons, depressions, pinnacles, and seamounts. Depth ranges from surface to 451 fm (most occur in 80 to 200 fm).		U	U	U		H	H	M
Kelp rockfish *Sebastes atrovirens*	Inhabiting shallow waters, adults are primarily residential in kelp forests and on the bottom near rocky areas and are considered parademersal. Common at depths of 5 to 7 fm, but found up to 25 fm with a distribution mostly off the coast of California.				U				H
Aurora rockfish *Sebastes aurora*	Adults and juveniles are found in soft- and hard- bottom habitats on the continental slope/basin. Distribution ranges from Vancouver Island, British Columbia to Cedros Island, Baja California. Depth ranges from 68 to 420 fm.		U	U	U		H	H	H
Redbanded rockfish *Sebastes babcocki*	Thought to associate with both soft substrata and hard-bottom substrata, and in crevices between boulders. This deepwater species has been caught in the 50 to 342 fm range and is found from Amchitka Island, Alaska to San Diego, California.				U				H
Silvergray rockfish *Sebastes brevispinis*	Inhabits the outer shelf-mesobenthal zone on a variety of rocky-bottom habitats. Found at the surface to 205 fm, from the Bering Sea to Baja California.				U				L
Shortraker rockfish *Sebastes borealiz*	Deepwater species inhabiting the middle shelf to the mesobenthal slope and common on the bottom from 100 to 478 fm. Distribution from the Aleutian Islands and down to Point Conception, California				U				H
Gopher rockfish *Sebastes carnatus*	These are shallow-water benthic fish that inhabit rocky reefs, kelp beds, and sandy areas near reefs. Common depth from surface to 9 fm and mostly limited to the California coast.		U	U	U		H	H	H
Copper rockfish *Sebastes caurinus*	Occur in nearshore waters, from the surface to 100 fm. Found on or near natural rocky reefs, boulder fields, artificial reefs, oil platforms and rockpiles; usually directly on the bottom with reefs or kelp bed areas. May move inshore to release their young.				U				H
Greenspotted rockfish *Sebastes chlorostictus*	Associated with soft-bottom habitats and also with rock outcrops, reefs, caves, and crevices. Range is from Washington to Baja California with depths 27-150 fm			U	U			H	L
Black and yellow rockfish *Sebastes chrysomelas*	Inhabits holes and crevices in rocky areas. Found in intertidal areas and depths to 20 fm.		U	U	U		H	M	M
Starry rockfish *Sebastes constellatus*	Usually found on reefs. Viviparous, with planktonic larvae and pelagic juvenlies. Limited distribution along the California coast from north of San Franciscon to Baja. Depth ranges from 13 – 150 fm.			U	U			U	M
Darkblotched rockfish *Sebastes crameri*	Adults are associated with muddy areas near cobble or boulders. Found at depths of 14 to 328 fm from the Bering Sea to Catalina Island, California.		U	U	U		H	H	H

Splitnose rockfish *Sebastes diploproa*	Associated with offshore mud habitats near isolated rock cobble and boulder fields. Most common at 50 to 250 fm. Young occur in shallow water, often at the surface under drifting kelp, algae, and seagrass. Emigration from surface waters occurs primarily in May and June.		H	U	U		H	H	H
Greenstriped rockfish *Sebastes elongatus*	Prefers a mixture of mud and rock bottom and found at depths of 14 to 232 fm. Distribution from Alaska to Baja California.			U	U			H	H
Widow rockfish *Sebastes entomelas*	All life stages are pelagic, but older juveniles and adults are associated with hard bottoms among rocks. This important commercial fish ranges from near Kodiak Island, Alaska to Todos Santos Bay in Baja California; from surface to 300 fm.			U	U			H	M
Pink rockfish *Sebastes eos*	Demersal, inhabiting rocky bottoms in isolated areas from Southern Oregon to Central Baja California. Depth range from 40 to 200 fm.				U				H
Yellowtail rockfish *Sebastes flavidus*	They are considered a middle shelf-mesobenthal species most common near the bottom. This schooling rockfish has a range from Unalaska Island, Alaska to San Diego, California and is found from the surface down to 300 fm.			U	U			H	H
Chilipepper rockfish *Sebastes goodei*	Most commonly associated with deep, high-relief rocky areas and along cliffs. A commercially important species in California found at the surface to 232 fm.			U	U			H	H
Rosethorn rockfish *Sebastes helvomaculatus*	Adults are mostly found in muddy areas adjacent to boulders, cobble, or rock. Depth range from 40 to 300 fm. Limited distribution from Alaska to Baja California.				U				L
Squarespot *rockfish* *Sebastes hopkinsi*	They are reef-associated, in areas with cobble and have a depth range of 2 to 120 fm.			U	U			H	H
Shortbelly rockfish *Sebastes jordani*	Can be found in large schools, offshore and off smooth bottom areas near the shelf break and sharp drop-offs. Depths of 0 to 191 fm.				U				H
Cowcod *Sebastes levi*	Adults are primarily found over high-relief rocky areas. Juveniles prefer soft bottom habitats and those consisting of low-relief rocks. Mostly found off California at depths of 11 to 200 fm.			U	U			H	L-M
Quillback rockfish *Sebastes maliger*	A common, shallow-water benthic species, from subtidal depths to 150 fm. Young occur along shores and adults usually in deeper waters.			U				H	
Black rockfish *Sebastes melanops*	Adults inhabit midwater and surface areas over-high relief rocky reefs, in and around kelp beds, boulder fields, pinnacles, and artificial reefs. Larvae and young juveniles are pelagic.			M	U			H	H
Blackgill rockfish *Sebastes melanostomus*	An aggregate species, usually inhabiting deep rocky-or hard-bottom habitats along steep drop-offs. Larvae inhabit the upper mixed layer of water, juveniles are pelagic (associated with flat bottoms) and migrate shoreward. Spawn from January to June.		U	U	U		H	H	H

		Eggs c/	Larvae c/	Juvenile c/	Adult c/	Eggs c/	Larvae c/	Juvenile c/	Adult c/
Vermilion rockfish *Sebastes miniatus*	Found over rocks, along drop-offs, and over hard bottom. Adults inhabit rocky reefs at depths of 8 to 150 fm. Larvae are pelagic and found near the surface for three to four months, and are frequently associated with algae.				U				H
Blue rockfish *Sebastes mystinus*	Strong affinity for kelp forests. Adults inhabit midwater and surface areas around high relief rocky areas, within and round the kelp colony, and around artificial reefs. Common depth range of 33 to 167 fm. Larvae and early stage juveniles are pelagic, and older individuals are semi-demersal or demersal.		L	U	U		H	H	H
China rockfish *Sebastes nebulosus*	Occur both inshore and along the open coast from 1 to 75 fm. Most Juveniles are pelagic, but adults are sedentary, associated with rocky reefs or cobble. They are residential and associated the bottom, crevices, and kelp beds.			U	U			H	H
Tiger rockfish *Sebastes nigrocinctus*	Found at depths of 5 to 150 fm. Juveniles are pelagic, common near water surface with algae mats and plants. Adults are semi-demersal. Often found in caves, off cliffs, and on floors. Solitary, may be territorial.				U				H
Speckled rockfish *Sebastes ovalis*	They occur in midwater over rocks and are also found near the bottom on reefs and among boulders. Depths range from 17 to 200 fm.			U	U			H	H
Bocaccio *Sebastes paucispinis*	Benthic juveniles and adults are found around vertical relief; over sand-mud bottoms with little relief; and in areas with mixtures of rocks and boulders, rock ridges, and rocks and boulders among mud. Most common at depths of 40 to 175 fm. Larvae and small juveniles are pelagic; large juveniles and adults are semi-demersal.		L	U	U		H	H	M
Canary rockfish *Sebastes pinniger*	Most abundant above hard bottoms, usually 50 to 110 fm. In its southern range, it is a reef associated species. Larvae and juveniles are pelagic. Young of the year can be found in tide pools, and can be associated with artificial reefs and interfaces between mud and rock. Juveniles descend deeper as they mature. Capable of large latitudinal movements.			U	U			H	H
Redstripe rockfish *Sebastes prorigger*	Generally found off the bottom over both high- and low-relief rocky areas. Depths range from 7 to 232 fm (most common at 70 to 150 fm).				U				H
Grass rockfish *Sebastes rastrelliger*	Common in nearshore rocky areas, along jetties, and in kelp and eelgrass. Residential species at shallow depths.			U	U			H	H
Yellowmouth rockfish *Sebastes reedi*	Found over rough bottoms from the Northern Gulf of Alaska to the south of Crescent City, California, with a depth range from 75 to 200 fm. More common at 100 to 200 fm.			U	U			H	M
Rosy rockfish *Sebastes rosaceus*	These fish are solitary bottom-dwellers found over hard, high-relief areas and at low-relief spots among rocks and sand. Depths range from 27 to 150 fm.			U	U			H	H
Yelloweye rockfish *Sebastes ruberrimus*	Inhabits rocky reefs and boulder fields from Prince William Sound, Alaska to Ensenada, Baja California. An important commercial species ranging from 8 to 300 fm.			U	U			H	H

		Eggs c/	Larvae c/	Juvenile c/	Adult c/	Eggs c/	Larvae c/	Juvenile c/	Adult c/
Flag rockfish *Sebastes rubrivinctus*	These demersal fish inhabit rocky areas and have a depth range of 0 to 302 meters.			U	U			M	H
Bank rockfish *Sebastes rufus*	Juveniles are parademersal and prefer mixed mud and rock habitats. Adults can be found on rocky reefs, among boulder fields, cobble, and mixed mud-rock bottoms. Depths range from 17 to 135 fm.			U	U			H	L
Stripetail rockfish *Sebastes saxicola*	A dominant soft-bottom fish. Pelagic juveniles, with a narrow depth range of 27 to 30 fm, are associated with sandy bottoms. Adult depth ranges from 5 to 299 fm (most common 80-150 fm).			U	U			H	H
Sharpchin rockfish *Sebastes zacentrus*	An outer shelf-mesobenthal species preferring mud and cobble and mud and boulder substrata. Found at depths from 14 to 260 fm.		U	U	U		H	H	M
Shortspine thornyhead *Sebastolobus alascanus*	Juveniles occupy shallower waters than adults, usually over muddy bottoms near rocks. Adults are found on muddy bottoms and bottoms with mud and cobble/boulder mixes. A deepwater species, found at 10 to 833 fm.			U	U			H	H
Longspine thornyhead *Sebastolobus altivelis*	Juvenile and adults are demersal and occupy the sediment surface, preferably sand or mud. A deepwater species, found often at 110 to 960 fm.			U	U			H	H
Cabezon *Scorpaenichthys marmoratus*	Most abundant in estuaries where all life stages may be present. Found intertidally or in shallow subtidal areas in a variety of habitats, often in the vicinity of kelp beds, jetties, oil platforms, isolated rocky reefs or pinnacles, and shallow tide pools. Mostly utilize rocky bottoms and cobble substrata.				U				H
Sablefish *Anoplopoma fimbria*	Inner shelf-bathybenthal commercial species. Eggs, larvae, and young juveniles are pelagic. Older-juveniles and adults are benthopelagic on soft bottoms, commonly with mud and sea urchins. Often migratory, wide-ranging depths from 170 fm to 1,000 fm. Spawning occurs in the late fall and early winter in waters at depths >167 fm.	L	U	U	U	H	H	H	H
Lingcod *Ophiodon elongatus*	Occupy the estuarine-mesobenthic zone, from intertidal areas to 266 fm. Mostly inhabit slopes of submerged banks with seaweed, kelp and eelgrass beds. Spawning occurs from December through April, 2-5 fm below mean lower low water over rocky reefs in areas with a swift current.	H	U	U	U	H	H	H	H
Finescale codling (mora) *Antimora microlepis*	Inhabits the lower regions of the continental slope between 437 fm and 980 fm. Whether or not the species migrates extensively or uses the North American west coast slopes only as feeding areas is not known.				U				H
Kelp greenling *Hexagrammos decagrammus*	High affinity for rocky banks near dense algae or kelp beds, or in kelp beds. Larvae and small juveniles are pelagic, adults are demersal (but not usually below 11 fm). Juveniles associated with rocky reefs and microalgae. Newly hatched larvae move out of estuaries or shallow nearshore areas into open water. Spawning occurs in the fall.		M		U		H		M

		Eggs c/	**Larvae c/**	**Juvenile c/**	**Adult c/**	**Eggs c/**	**Larvae c/**	**Juvenile c/**	**Adult c/**
Pacific sanddab *Citharichthys sordidus*	Inhabit s inner continental shelf along the West Coast. Most abundant in 20 to 50 fm. Small juveniles prefer silty sand substrata and adults prefer sand and coarser sediments and low-relief rock bottoms. Spawning occurs late winter through summer.				U				H
Arrowtooth flounder *Atheresthes stomias*	Eggs and larvae are pelagic and juveniles and adults are demersal. Juveniles and adults are usually found on sand or sandy gravelly substrata, but occasionally over rock-relief sponge bottoms. Migrate from shallow-water summer feeding grounds on the continental shelf to deep-water spawning grounds over the continental shelf. Spawning occurs in the winter.	H	H	U	U	H	H	H	H
Petrale Sole *Eopsetta jordani*	Juveniles and adults are demersal. Adults migrate seasonally between deep-water winter spawning areas to shallower, spring feeding grounds. Found on sand and mud bottoms from 10 to 300 fm. Most abundant at 30 to 70 fm from April through October and at 150 to 250 fm during winter.			U	U			H	H
Rex sole *Glyptocephalus zachirus*	Abundant on sandy, muddy, and gravely bottoms. Also in complexes of mud and boulders. Cold temperate, upper-slope, outer-shelf flatfish with pelagic eggs and larvae. Move inshore in summer and offshore for spawning in winter and early spring.			U	U			H	H
Flathead sole *Hippoglossoides elassodon*	These sole inhabit soft, silty or muddy bottoms from 0 to 575 fm (common 55 to 135 fm). They can also be associated with mud mixed with gravel or sand.			U	U			L	L
Dover sole *Microstomus pacificus*	Innershelf-mesobenthal commercially caught species, mostly in waters <273 fm. Adults and juveniles have high affinity for soft bottoms of fine mud and sand. Commonly associated with mud and sea urchins. Eggs are epipelagic, larvae are epi-mesopelagic, and juveniles and adults are demersal. Spawning occurs in the spring near the bottom of the water. Females and juveniles migrate offshore to deeper waters in the fall.			U	U			H	H
English sole *Parophrys vetulus*	Shallow-water, soft-bottom, marine and estuarine environments. Spawning occurs in winter to early spring over soft-bottom mud strata, depths of 27-38 fm. Eggs and larvae are pelagic and adults are demersal		M	L	L		H	H	H
Starry flounder *Platichthys stellatus*	Occur in the inner continental shelf and shallow sublittoral communities. Older individuals occur from 75 miles upstream to the outer continental shelf. Juveniles prefer sandy to muddy substrata. Spawning occurs in late winter-early spring in estuaries or sheltered inshore bays with less than 25 fm.	L		U	L	H		H	H
Rock sole *Pleuronectes bilineatus*	Juveniles and adults are demersal and found primarily in shallow water bays and over the continental shelf on rocky, pebbly, or sandy bottoms form 0 to 200 fm. Most are caught in 20 to 40 fm.				U				H
Curlfin sole *Pleuronichthys decurrens*	Curlfin are found on soft bottoms from 4 to 291 fm, but usually are found in shallower waters.				U				H

4.1.4 Pacific Salmon Species

EFH for Pacific salmon species includes nearshore marine water and waters extending out 200 nmi to the EEZ boundary off the coasts of Washington, Oregon, and in California north of Point Conception. It also includes inland estuaries and freshwater streams, lakes, ponds, and other waterbodies that were historically accessible to salmon. EFH excludes habitats upstream from longstanding impassible barriers (waterfalls) and upstream from impassible barriers (dams) identified by PFMC (1999). Pacific salmon species with EFH in the marine, estuarine, and riverine project analysis areas include Chinook and coho salmon. This includes two ESA-listed coho salmon ESUs in portions of the analysis area as described below.

EFH for Chinook and coho salmon has been designated within the following watersheds that coincide with the proposed action riverine analysis areas: South Umpqua River (HUC 17100302), Coos River (HUC 17100304), Coquille River (HUC 17100305), and Upper Rogue River (HUC 17100307). EFH for Chinook salmon and coho salmon is also present in the Upper Klamath River (HUC 18010206) in California and Oregon, but construction of multiple dams on the mainstem Klamath River has made upstream areas impassible to anadromous fish (Hamilton et al. 2005). Habitats within the project area upstream from the Iron Gate Dam are not currently accessible to coho or Chinook salmon, but the Oregon Fish and Game Commission in July 2008 authorized the study of reintroduction of anadromous fish into the Klamath River system in Oregon. As of 2014, no action has been taken to actually remove these dams or transport fish upstream past the dams, so no further assessment of potential EFH effects in the Upper Klamath River watershed is provided in this BA.

Coho salmon within the riverine analysis area of the Upper Rogue River (HUC 17100307) watershed are within the SONCC coho salmon ESU, and their threatened status, environmental baseline, Project effects, and determination of effects under the ESA (species effects and effects to designated critical habitat) were addressed earlier in this BA in section 3.5.3. Likewise, section 3.5.4 evaluates coho salmon within the South Umpqua River (HUC 17100302), Coos River (HUC 17100304), and Coquille River (HUC 17100305) watersheds theat are within the Oregon Coast ESU, which are listed as threatened and with designated critical habitat under the ESA.

EFH for coho salmon of both listed ESUs is present within the riverine and marine analysis areas. The listed Oregon Coast coho salmon ESU is also present in the estuarine analysis area of Coos Bay.

Figure 4.1.4-1 shows the specific timing of life history phases for fall-run Chinook salmon within the estuarine and riverine analysis areas. Spawning does not occur within the Coos Bay estuary or the analysis area included for the Coos River. Spawning does occur within the Coquille River and tributaries, in the Rogue River mainstem and tributaries, and in the South Umpqua River mainstem and tributaries.

Specific timing and life history phases of the ESA-listed coho salmon are presented the main BA sections 3.5.3 (SONCC coho) and 3.5.4 (Oregon Coast coho) shown in (figures 3.5.3-1 and 3.5.4-1). Whereas adult coho in the SONCC ESU and Oregon Coast ESU begin upstream migrations in September, fall Chinook salmon in some watersheds begin as early as mid-July (Coos River and Coquille River) or early August. Similar to coho, fall Chinook salmon in the South Umpqua River begin upstream migrations in early September. Spawning in the South Umpqua mainstem begins as early as mid-September, but begins in October within tributaries to the South Umpqua. Fall Chinook salmon spawning in the Rogue River mainstem and tributaries also begins in October (see figure 4.1.4-1).

Figure 4.1.4-1 Approximate Timing of Fall Chinook Salmon Use of Streams and Estuaries in the Pipeline Project Area

Figure 4.1.4-2 shows the specific timing of life history phases for spring-run Chinook salmon within the riverine analysis areas. No life-phase timing of spring Chinook salmon is reported for the Coos Bay estuary or Coos River. Spawning does occur in the Coquille River and tributaries from September through mid-November. Spawning also occurs within the Rogue River mainstem and tributaries in October and November, as well as in the South Umpqua River mainstem from mid-September through January and in its tributaries from October through mid-January (see figure 4.1.4-2).

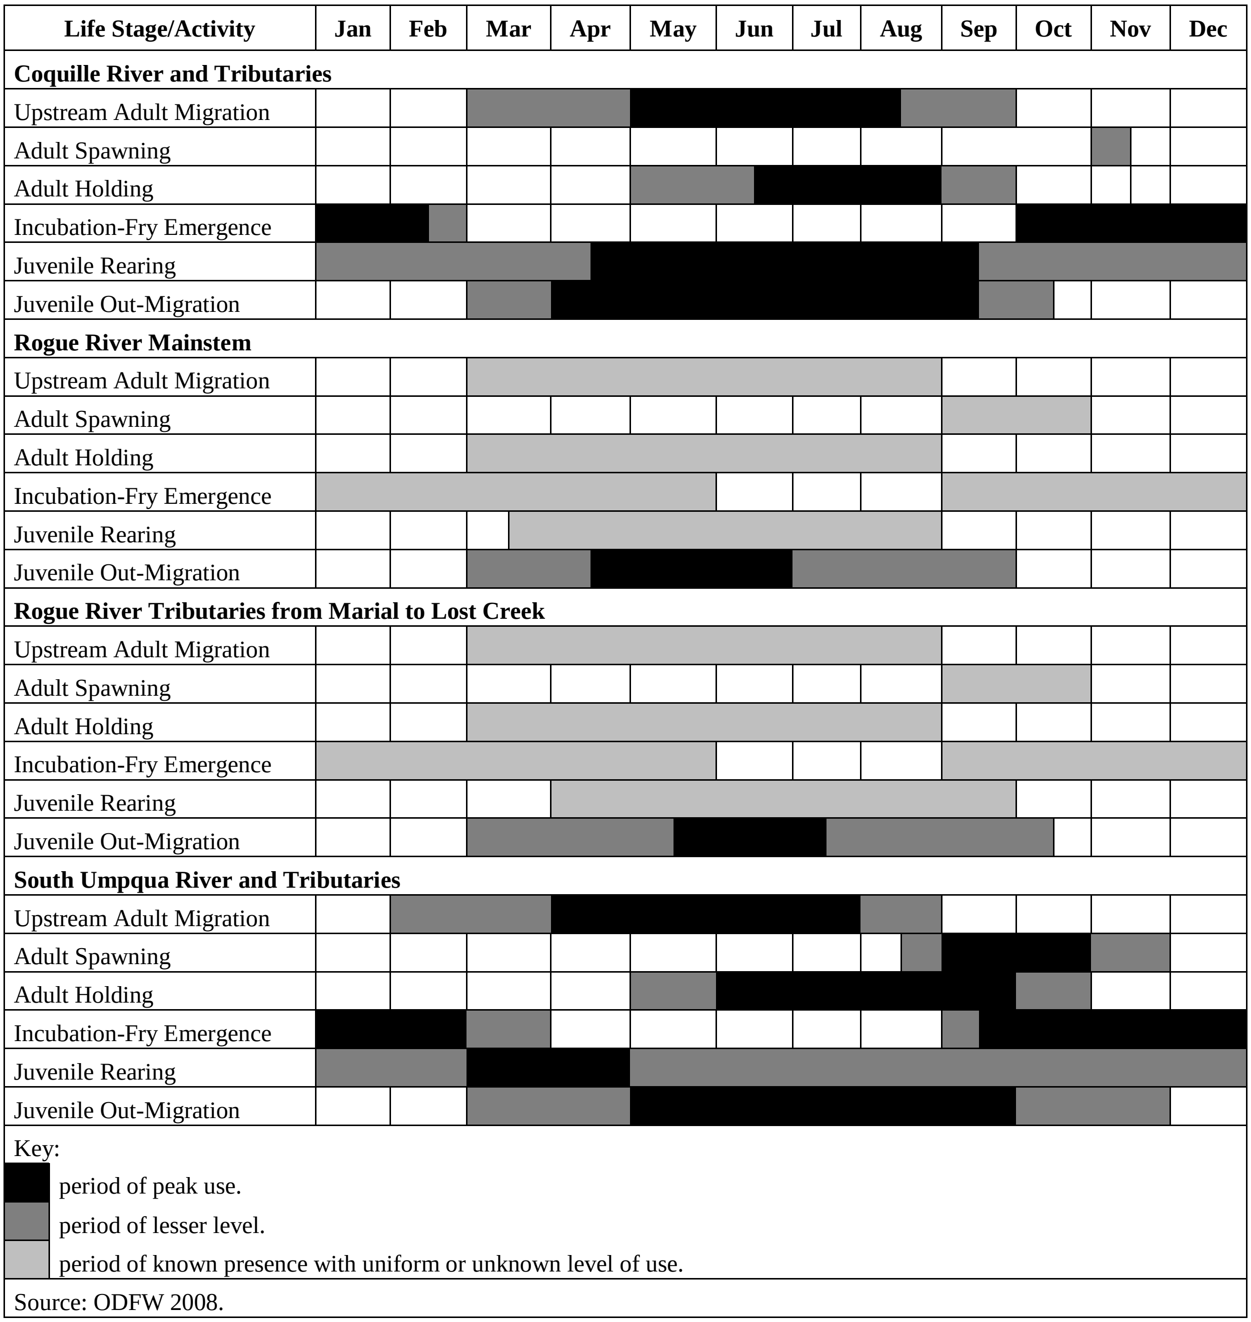

Figure 4.1.4-2 Approximate Timing of Spring Chinook Salmon Use of Streams in the Pipeline Project Area

4.2 ANALYSIS OF EFFECTS

Most of the Project effects to fish and their habitats are described in detail in BA effects discussions for the ESA listed fish species including green sturgeon (section 3.5.1.3), eulachon (section 3.5.2.3), SONCC coho salmon (section 3.5.3.3), and Oregon Coast coho salmon (section 3.5.4.3). While effects analyzed were specific to these species, the details of the type of effects are mostly comparable to other fish habitat groups in the same environment.

Since the four EFH fish management groups would have effects that are similar or the same across the three analysis areas (marine, estuarine, and riverine) in type and magnitude, the discussion below will focus on the level of specific effects within each analysis area. Where effects would be unique to each management group, these effects are called out.

4.2.1 Marine Analysis Area

The marine analysis area includes EFH for all four FMP fish groups and is the only analysis area where highly migratory species may be present. With the possible exception of adult common thresher shark, highly migratory species are likely to be absent from the marine environment near the entrance to Coos Bay. Project actions in this area that have the potential to affect these FMP groups are associated with underwater noise and potential fuel, gas, or oil spills from LNG carriers in transit to and from the LNG Terminal. A more detailed discussion of direct, indirect, and cumulative effects of the Project on fish and their associated habitat requirements in the marine analysis area is included in section 3.5.

4.2.1.1 Acoustic Effects

Underwater noise produced by LNG carriers transiting the marine analysis area may affect fish of all four FMP groups. Some of the LNG carriers that would call on the LNG Terminal generate more noise than the LNG carriers built in 2003 with 138,028 m^3 capacity that produced sound levels (with one standard error) of 182 ± 2 dB re: 1 µPa @ 1 meter as reported by Hatch et al. (2008). Hatch noted that LNG carriers produced nearly the highest noise level of any type of major vessel monitored.

State agencies in Washington, Oregon, and California along with federal agencies have developed interim noise exposure threshold criteria for pile-driving effects on fish (WSDOT 2011a; Fisheries Hydroacoustic Working Group 2008; Popper et al. 2006). These threshold criteria are considered levels below which injury effects would not occur to fish from in water noise. These thresholds should thus be suitable for all forms of in-water noise. Interim noise exposure threshold criteria for pile driving effects on fish include: 1) a cumulative sound exposure level (SEL_{cum}) of 187 dB re 1 μPa^2 s for fishes weighing more than two grams, 2) a SEL_{cum} of 183 dB re 1 μPa^2 s for fishes less than two grams, and 3) a single-strike peak level (SPL_{peak}) of 206 dB re 1 µPa for all sizes of fishes (WSDOT 2011a). As described by Hatch et al. (2008), LNG carriers built in 2003 produced sound levels (with one standard error) of 182 ± 2 dB re: 1 µPa @ 1 meter that attenuated to 160 dB at 35 ± 11 meters and to 120 dB at 16,185 ± 5,359 meters.

In-water noise values generated by LNG carriers transiting the marine analysis area for the proposed project would attenuate to levels below the effect thresholds noted above a few meters from a vessel's hull and, therefore, would not cause direct harm to fish. Very small fish within 1 meter (3 feet) of an LNG carrier hull that are exposed to LNG carrier noise for extended periods, however, could be adversely affected. Since most fish can easily avoid LNG carriers in transit, noise exposure typically would be very brief, further reducing the potential for adverse effects. Therefore, underwater noise generated by LNG carriers transiting the marine analysis area is not expected to adversely affect EFH of the four FMP groups.

4.2.1.2 Fuel or Oil Spills at Sea

The LNG carriers use either a steam or duel fuel diesel electric propulsion system that is primarily fueled by natural boil-off gas. Fuel (e.g., diesel) used for back-up generation for LNG carrier propulsion and oil or hydraulic fluids used for mechanical equipment could possibly leak or be spilled while the carriers are in transit. A maximum of 120 LNG carriers per year would traverse the marine analysis area to call at the LNG Terminal. The low volumes of petroleum oils and fuel on LNG carriers greatly reduces the risk of impacts on the marine environment from petroleum spills. The Federal Water Pollution Control Act, as amended by the CWA (33 U.S.C. 1251–1387), prohibits the discharge of oil upon the navigable waters of the United States. Also, LNG carriers calling on the LNG Terminal would be required by the Coast Guard to have a vessel response plan in order to be adequately prepared for accidental spills. As reported by Pacific States/British Columbia annual reports (2002), the number of oil spills reported from fishing, recreational and other harbor marine vessels in Oregon ranged from about 9 to 65 per year, which is fairly infrequent considering that thousands of marine vessels, both recreational and commercial utilize Oregon coastal marine waters. As a result, accidental spills or release of fuel, lubricants, or hydraulic fluids within the marine analysis area are not expected to adversely affect any EFH of the four FMP groups.

4.2.2 Estuarine Analysis Area

The estuarine analysis area of Coos Bay includes habitat and fish from the coastal pelagic, groundfish, and Pacific salmon FMP groups. Effects to EFH in this area would be associated with LNG carrier transit into and out of the bay; slip, access channel, Navigation Reliability Improvements, and associated upland facility construction and operation; HDD installation under the Coos Bay estuary; and LNG carrier water intake and discharge while at the loading dock. A summary of marine and estuarine habitat areas temporarily and permanently affected by construction and operation of the LNG Terminal is presented in tables 2.3-1 and 2.3-2 of JCEP's Resource Report 2. Additional detailed discussion of direct, indirect, and cumulative effects of the Project on fish and associated habitats in the estuarine analysis area is included in section 3.5.

4.2.2.1 Turbidity Effects from Dredging in Coos Bay

Resuspension of sediments and temporary increases in turbidity above Coos Bay background levels would occur while installing and removing the temporary earthen berm at the LNG Terminal slip and while dredging the access channel and Navigation Reliability Improvements.

Turbidity increases would be limited to the time required to complete each of the respective Project components within the ODFW in-water work window (October 1 to February 15) and would be subject to water quality compliance standards.

Construction of the LNG Terminal slip would require excavation and dredging of Coos Bay's shoreline near Jordan Cove. Excavation of the slip would be primarily conducted in isolation from the waters of Coos Bay by leaving a temporary earthen berm in place at the mouth of the slip during excavation. Release of turbid waters into the bay would be essentially prevented during excavation of the slip, except during a short period when the earthen berm is removed to connect the slip to the access channel and Federal Navigation Channel (FNC). Details on dredging quantities and methods, sedimentation and turbidity levels, and other Project related effects on fish habitat are described in section 3.5.1.3 and in JCEP's Resource Reports 2, 3, and 7.

The effects of temporary siltation and sedimentation on EFH from removing the earthen berm at the mouth of the Terminal slip and while dredging the access channel would be similar to those that would result from maintenance dredging of the Coos Bay FNC by the USACE. The quantity of dredge material from the maintenance of the FNC averages about 900,000 cubic yards (cy) per year. In comparison, JCEP would dredge a total of about 1.8 million cy (mcy): 0.5 mcy when removing the earthen berm and 1.3 mcy when dredging the access channel to a design depth of minus 45 feet (NAVD88) plus 1.7 feet for advanced maintenance dredging and 2 feet for allowable overdepth. Dredging methods would include cutterhead suction dredge, clam shell dredge, and/or mechanical excavation with backhoe.

Turbidity was modeled for the capital (i.e., new construction) dredging operations based on the anticipated geotechnical and environmental conditions for this project using the COE's DREDGE model and two dimensional numerical model Mike21 (see discussion in section 3.5.1.3, green sturgeon). Increases in turbidity in the bay due to construction-related dredging would be for a short period of time (4-6 months) affecting a restricted area. Modelling at the access channel has demonstrated the maximum turbidity plume extent, defined by the simulated 10 NTU above background contour, to be approximately 780 and 750 feet when using a cutter suction and clamshell dredges respectively. (Moffatt & Nichol 2017c). When dredging the access channel, the turbidity plume would be primarily elongated in an upstream or downstream direction, depending on the tidal cycle. To a more limited extent, the plume also would extend laterally from dredging sites. As dredging operations approach the FNC (where water velocities are greater), the turbidity plume would extend farther downstream (during an outgoing tide) or upstream (during an incoming tide) than it would near the mouth of the terminal slip where water currents are lower.

To minimize the generation of TSS and turbidity during dredging, operational and environmental controls would be employed to assure compliance with water quality criteria stipulated in the CWA Section 401 Certification issued by ODEQ. Such controls may include ceasing dredging, decreasing cutterhead speed, increasing the suction flow rate and using different size or type of dredge (e.g., use of a cutter suction dredge or closed clamshell bucket to minimize turbidity generation), lowering the crest elevation, and/or avoiding sediment stockpiling during peak ebb conditions (Moffatt & Nichol 2017o). In addition, containment systems on scows and/or barges used to transport material from the eelgrass mitigation site, or other dredge locations, will minimize the release of turbid decant water back into the bay. All dredging activities that are not isolated from Coos Bay will be conducted during the in-water work window that will extend from October 1st to February 15th to limit potential impacts to sensitive life stages of fish.

A Turbidity Monitoring and Management Plan (TMMP) will be prepared during final design. The TMMP will be finalized after the means and methods of dredge operations are confirmed by the selected contractor. The primary goal of the TMMP will be to manage proposed dredging operations for the Project consistent with DEQ water quality standards and permit requirements. Provisions of the DEQ-approved TMMP will be followed during all dredging activities.

Juvenile life stages of coho and Chinook salmon would be less common in Coos Bay during the fall and winter in-water work window. Exposure to sedimentation and turbidity from dredging, therefore, would be minimal. Adult coho and Chinook salmon, however, migrate into the estuary in the fall and early winter concurrent with in-water construction and maintenance activities (see life history figures 4.1.4-1 and 4.1.4-2 above for Chinook salmon and figure 3.5.3-1 for SONCC coho and figure 3.5.4-1 for Oregon Coast coho salmon). Smaller fish, with a limited swimming ability, would be less able to avoid turbid waters within about 200 feet of dredging operations. Turbidity exposure to adult or juvenile fish would be short-term and localized and may be mitigated to an immeasurable extent as fish avoid underwater noise generated near dredging areas.

Benthic and epibenthic biota would be directly and indirectly affected by dredging, sedimentation, turbidity, and from other in-water construction activities. Construction of the MOF, slip, and access channel would result in the long-term loss of intertidal to shallow subtidal, salt marsh, and eelgrass habitats as described in greater detail in section 3.1.4.2 of JCEP's Resource Report 3. Temporary impacts to deep subtidal habitats would result from dredging the Navigation Reliability Improvements.

While both long- and short-term losses of such habitat from dredging would adversely affect EFH for the three FMP groups, such impacts would be minor relative to the overall availability of EFH in Coos Bay. EFH disturbed by dredging the Navigation Reliability Improvement sites, access channel and the earth berm at the Slip entrance, would recover to a limited extent within a month to a year subject to future disturbance (Newcombeand Jensen 1998, Swartz et al. 1980, as cited in Wilber and Clarke 2007). The Eelgrass Mitigation Site, although requiring several years to develop, would eventually improve the ecological function of the existing eelgrass community and contribute to a long-term increase in EFH for all three FMP groups.

In summary, capital dredging may adversely affect EFH for juvenile and adult fish from the three FMP groups. This is based on the predicted levels of turbidity from dredging in Coos Bay relative to background levels, the short-term, localized, but ongoing exposure of fish to such conditions during the possible four in-water work windows.. Maintenance dredging plans are subject to subsequent regulatory consultations and permit approvals associated with the Project operations phase.

4.2.2.2 Turbidity Effects from Temporary In-water Construction

In-water construction activities are expected to temporarily increase concentrations of sediment and turbidity. Such increases would be localized and limited to the time required to complete each of the following Project components within the ODFW in-water work window:

- Temporary Material Barge Berth (TMBB),
- Material Offloading Facility (MOF),
- Pile Dike Rock Apron
- Trans Pacific Parkway/US-101 Intersection Widening,

- APCO Site access bridge construction,
- replacement of anchoring systems for existing meteorological ocean data collection buoys as well as addition of anchoring systems for two new buoys,
- establishment of hydraulic connections to the Kentuck Project for estuarine habitat mitigation, and
- creation of the Eelgrass Mitigation site.

Benthic and epibenthic biota would be directly and indirectly affected by sedimentation, turbidity, excavating the TMBB, fill associated with the MOF, and from other in-water construction activities. Construction of the MOF and Pile Dike Rock Apron would result in the long-term loss of intertidal to shallow subtidal, salt marsh, and eelgrass habitats as described in greater detail in section 3.1.4.2 of JCEP's Resource Report 3 for the MOF. Temporary impacts to intertidal and deep subtidal habitats, including eelgrass communities, also would result from in-water construction including the work bridge piling for the APCO Site access bridge, the Eelgrass Mitigation Temporary Dredge Line, the Kentuck Project, and the APCO 2 Temporary Dredge Transfer Line.

While both long- and short-term losses of such habitat would adversely affect EFH for the three FMP groups, such impacts would be minor relative to the overall availability of EFH in Coos Bay. The Eelgrass Mitigation Site, although requiring several years to develop, would eventually result in a long-term increase in habitat that would benefit EFH for all three FMP groups.

4.2.2.3 Turbidity Effects – LNG Carriers in the Waterway

Propwash from propellers of LNG carriers and tug boats, as well as ship wakes (waves) breaking on shore, may cause an increase in shoreline erosion and turbidity over existing conditions. Depending on the intensity of such wave energy and bottom scour, eroded materials could be re-suspended within the water column resulting in disturbance, displacement, and injury to nearshore fish and benthic communities. Potential effects to the abundance, diversity, and health of benthic biota could alter food availability and feeding conditions for foraging and migrating fish species. Depending on the magnitude of vessel-generated waves and the location and character of the shoreline they encounter, potential fish stranding also could result from certain vessels in transit in Coos Bay (see section 4.2.2.5).

To address such concerns, potential wake effects of LNG carriers and tugs, with up to 120 inbound and 120 outbound trips per year, were evaluated through model studies by JCEP (see section 3.5.1.3). The model results indicated LNG carrier transit would contribute to existing shoreline erosion caused by wind and existing vessel traffic, however, the magnitude would be small and much less than what naturally occurs from wind-generated waves. The height of waves along the shoreline were predicted to range from 0.6 to 0.8 feet for outbound tugs periodically traveling at high speeds (up to 10 knots) to meet incoming LNG carriers. Wave heights associated with typically slower LNG carrier-tug transits were predicted to be lower at 0.2 to 0.6 feet. Therefore, project-related wakes and shoreline erosion would likely be within the range of the natural annual variability of wind waves that have heights ranging from 0.5 to 3 feet (Moffatt & Nichol 2017d).

Modeled propeller-generated bottom disturbance from LNG carrier passages indicated some increases in bed disturbance within 0.25 to 0.5 mile of the slip along a narrow band (about 80 feet wide) in the deep mid-channel where coarse sediments occur. This would result in a limited amount of turbidity that would be localized and within the range of seasonal background levels in Coos Bay. Modeled tugboat operations indicated some bottom disturbance also would be likely during docking. The extent of bottom disturbance in the access channel would be limited to a depth of nearly 0.5 feet below the bed surface over a small area of about 100 by 50 feet. In most cases, the actual disturbance would likely be much less than this because of the conservative assumptions used in the model, including a lack of slope protection. Slope protection is planned for the north side and sections of the east side of the slip, reducing potential bottom scour. Again, elevated suspended sediment and turbidity levels during LNG carrier docking are expected to be localized resulting in short-term effects to benthic communities and fish habitat in the docking area. Overall, while the magnitude, extent, and frequency of propeller scour, suspended sediment, and turbidity resulting from Project-related wave energy and propwash, may be minor, it may adversely affect EFH for the three FMP groups.

4.2.2.4 Turbidity Effects – Pipeline Construction with HDD

Coos Bay would be crossed by two HDDs, one from MP 0.28 to MP 1.00 (West HDD), the other from MP 1.46 to MP 3.02 (East HDD). The Coos River (a tributary to the estuary) would also be crossed using HDD at MP 11.13. At that location, the Coos River is under tidal influence.

Drilling requires use of a drilling mud for lubrication of the bit and removal of cuttings. A non-toxic, biodegradable bentonite clay mixture makes up drilling mud. Because the drilling mud is under pressure during drilling, if the bit encounters substrate fractures or channels, it is possible for bentonite to escape from the hole (termed a “inadvertent return”). Bentonite can escape to the surface through fractures in the drilled substrate. Benthic organisms, which coho salmon would feed on, could also be affected by burial. However, bentonite is more likely to stay in suspension than settle if compared to common bottom sediment; therefore, in flowing water areas, effects to benthic organisms from burial from inadvertent return are likely to be low.

The horizontal crossing length of the West HDD would span 5,192 feet, extending from the North Spit to the southeast, crossing the Coos Bay navigation channel and terminating at North Point in North Bend, Oregon. The HDD profile would pass approximately 158 feet below the railroad trestle bridge and approximately 138 feet below the deepest part of the navigation channel. The depth and the locations of the railroad trestle foundations are unknown at this time (GeoEngineers 2017a). The feasibility analysis for the West HDD anticipates a relatively low risk of hydraulic fracture and drilling fluid surface releases occurring during construction due to geologic conditions along the drill path. However, there is a risk of hydraulic fracture and drilling fluid surface release within about 150 feet of either end of the HDD due to the anticipated loose sand and decreased depth of cover during drilling operations.

The horizontal crossing length of the East HDD would span 8,972 feet extending from North Point in North Bend, Oregon eastward across Coos Bay and ending at the mouth of Kentuck Slough. Surface conditions at North Point at the west end of the HDD consist of a relatively flat ground surface covered with fill stockpiles. The east end of the HDD would be located within a flat grass vegetated area in Kentuck Slough Valley. The proposed depth of the pipeline would be 210 feet below ground surface. The risk can be reduced by reaming the hole from both ends of the crossing. In general, GeoEngineers (2017a) expects the risk of drill hole instability along the HDD drill paths to be relatively low. Minor hole instabilities may be encountered within the very loose to loose soils expected along the upper portions of the HDD profile at the east end near Kentuck Slough, but that condition would not jeopardize the successful installation of the product pipe.

For construction using HDD across the Coos River (GeoEngineers 2017b), the design length of the Coos River HDD crossing would be approximately 1,602 feet. The proposed entry point would be located approximately 500 feet from the north bank of the Coos River and the exit point approximately 630 feet from the south bank. The entry and exit points would allow for adequate depth beneath the Coos River. The preliminary design provides a minimum of 50.3 feet of cover below the Coos River. GeoEngineers' evaluation determined that the construction of the Coos River HDD crossing is likely feasible. GeoEngineers opined that there is a relatively high risk of hydraulic fracture and drilling fluid surface releases along the first 500 feet and last 300 feet of the HDD, respectively. However, the risk of drilling fluid surface release to the Coos River would be relatively low.The locations where any inadvertent return may occur in the Coos River would be affected less because of the dilution factor of the large volume of water from any spill. PCGP's *Drilling Fluid Contingency Plan for Horizontal Directional Drilling Operations* (see appendix D) describes how the drilling operations would be conducted and monitored to minimize the potential for inadvertent drilling mud releases. The HDD Contingency Plan also includes procedures for cleanup of drilling mud releases. If significant concentrations are found during monitoring as a result of a release, possible corrective measures would be taken as described for Oregon Coast Coho in section 3.5.4.3 (Direct and Indirect Effects – Estuarine Analysis Area).

4.2.2.5 Construction Runoff and Stormwater Discharge from LNG Terminal

The type of effects to EFH from upland facility stormwater discharge during construction and operation are described in detail in sections 3.5.1.3 and 3.5.4.3. During construction, impacts on marine resources could result from the clearing of vegetation at the terminal, erosion and sediment runoff, and potential hazardous substance spills. While no streams are present in the upland portion of the LNG Terminal, the removal of existing vegetation could modify the character and amount of water runoff into the bay. JCEP would prevent uncontrolled releases of sediment runoff during construction by implementing the erosion control and revegetation measures described in JCEP's ESCP. Additionally, accidental spills of hazardous materials (e.g., equipment fuel, oils, and paints) during construction could have effects on aquatic resources in the bay. JCEP prepared a draft site-specific SPCCP to control accidental releases of hazardous materials and manage potential adverse effects to EFH and fish species in Coos Bay.

Stormwater discharge has the potential to contain chemicals toxic to EFH species present in the Coos Bay estuary and nearshore ocean, excluding highly migratory species. The applicant's NPDES permit would require monitoring of discharges to ensure they do not modify state water quality standards of the receiving water. The 1200-C stormwater permit application states, "The permit registrant must not cause a violation of instream water quality standards" (ODEQ 2007).

Since the water quality standards are designed to protect aquatic resources, including EFH species, the applicants are to ensure the standards are not exceeded, and therefore do not cause adverse harm to aquatic resources. Thus, compliance monitoring to ensure all terms and conditions of the permit issued by the state also would ensure that aquatic resources are protected. However, it is known that stormwater runoff can result in chemical concentrations at the point of discharge that are in excess of EPA water quality criteria (WDOE 2009). The general characteristics of the stormwater management system is described below.

The proposed stormwater management system is designed to direct flows that do not come into contact with any equipment containing potential contaminants (grease or lubrication oil) to designated areas for treatment.. Treatment of runoff from areas that have low potential for oil or grease contamination will generally consist of on-site infiltration to treat for suspended solids. Cartridge filter vaults may also be used in some locations. Stormwater collected in areas that are potentially contaminated with oil or grease will be pumped or will flow to the oily water system. Primarily, these localized drains are located around equipment to contain grease and/or lubrication oil. Water and oil from the collection sump would overflow to the oily waste separator package equipped with plate type separation devices to remove any oil and grease washed down from the facility equipment. Recovered oil and grease would be held in the sump and periodically pumped directly to storage drums for disposal. The oily water system will flow to the oily water separator package(s) before being treated and discharged to the IWWP and ocean outfall. The facility will be designed to provide drainage of surface water to designated areas for disposal in accordance with 49 CFR § 193.2159. Stormwater collection and treatment facilities will be designed to meet regulatory requirements from the National Marine Fisheries Service ("NMFS") and ODEQ.

The proposed oil and grease treatment system is designed to limit discharges of oil and grease and would ultimately need approval from the State to obtain the NPDES permit. The treatment system function is an additional level of protection for inadvertent spills that come into contact with stormwater. The facility is not designed to intentionally mix oil and grease with stormwater and there are no continuous discharges of oil and grease from the LNG Terminal. Discharges from the LNG Terminal that could contain oil and grease would only occur during stormwater events. The following is a description of stormwater management systems for specific Project components.

Stormwater Management at LNG Terminal Site

The stormwater management plan has been prepared to address stormwater system design, which would require approval from ODEQ (see Storm Water Management Plan appended to JCEP's Resource Report 2). Impervious surfaces associated with the LNG Terminal site include concrete at operational laydown areas, vehicle offloading areas, secondary containment areas, and working areas for operational maintenance. General surfacing in other areas where operational maintenance access would potentially be required would be dense-graded aggregate. In the areas of the Administration building and the Southwest Oregon Regional Safety Center (SORSC) building, finished surfaces would consist of asphalt for the parking lots and concrete for the helipad. The gas metering station would be surfaced with dense-graded aggregate. Runoff would be separated into either the stormwater system or the oily waste system. Stormwater with a high potential to encounter oil and grease pollution would be contained via curbs or other means and routed to an oil/water separator prior to being conveyed to the

Industrial Wastewater Pipeline (IWWP) according to the applicable the NPDES permit requirements. For areas of the site where stormwater has a low potential to encounter oil and grease pollution, the first flush of stormwater would be treated onsite by either infiltration facilities, flow-through type cartridge filter devices, or vegetated side slopes. Infiltration facilities would provide treatment for the majority of the stormwater falling on the site. The facilities would be designed to capture and infiltrate all stormwater for 100% of the 2-year, 24-hour storm. Overflows from the infiltration facilities would be routed to pipe outfalls in the slip and Coos Bay. For locations that are not feasible to infiltrate, stormwater would be routed to cartridge filter devices, where the treated effluent would be discharged to Coos Bay through an NPDES permitted outfall. Stormwater from access roads to the site would flow through vegetated side slopes or ditches for treatment prior to being discharged to natural grade.

Industrial wastewater would be conveyed to the Port's existing ocean outfall, pursuant to the NPDES permit issued by the ODEQ. Stormwater collection and treatment facilities would be designed in consultation with NMFS and the ODEQ.

During construction, spills or leaks of hazardous liquids such as fuel or oil associated with construction equipment have the potential to reach surface waters including Coos Bay. Potential adverse effects from a fuel spill would likely be short-term and localized, affecting EFH species within the estuarine analysis area. Petroleum-based contaminants such as fuel, oil, and some hydraulic fluids contain polycyclic aromatic hydrocarbons (PAHs) which can be acutely toxic to the aquatic environment for fishes, and can also cause lethal and sublethal effects to aquatic organisms (Breteler et al. 1985). Potential impacts from such spills would be avoided or greatly reduced by regulating storage and refueling activities, and by immediately implementing cleanup should a spill or leak occur. To avoid and control the potential contamination of surface water, the preliminary SPCCP prepared for the construction phase; describes the measures that would prevent and minimize the potential for accidental releases of hazardous materials and to establish protocols concerning containment, remediation and reporting of any releases that occur. The SPCCP would be included as part of the NPDES permit.

Operation of the LNG Terminal would not require or produce large quantities of hazardous materials. Solvents and paints would be used during normal maintenance activities and would be stored in specialized containers with secondary containment to prevent spills. Within the LNG Terminal would be a system of curbs, drains, and basins that contain and collect accidental spills or leaks thus preventing releases into Coos Bay that otherwise could impact water quality and reduce feeding opportunities for aquatic species within the estuarine analysis area. Operations at the LNG Terminal would comply with the SPCCP to minimize the potential for accidental releases of hazardous materials and to establish proper protocols concerning minimization, containment, remediation, and reporting should releases occur. The SPCCP would meet the requirements of 40 CFR Part 112.

In the event of a spill, any hazardous materials from the concrete containment basins would be collected and trucked offsite to appropriate disposal areas. In the unlikely event of an accidental LNG spill, no effects on EFH are anticipated since LNG is not toxic, is not soluble in water, and, if spilled on water, would vaporize and rise when exposed to the warmer atmosphere.

During operations, LNG carriers calling on the LNG Terminal could have accidental releases of fuels or other contaminants commonly used on ships. There is no planned bunkering (loading of fuel oils) for the LNG carriers and these products are kept in relatively small quantities on ships. Therefore, such spills would be limited to small inadvertent spills of petroleum-based fuels and lubricants from equipment onboard that would be managed according to the carrier's oil spill response plan. Depending on the timing, weather conditions, and the efficiency of the response and cleanup, localized adverse impacts may still occur depending on the proximity to aquatic habitat.

Stormwater Management at Trans Pacific Parkway/US-101 Intersection Widening

Stormwater generated as a result of new impervious area at the Trans Pacific Parkway/US-101 Intersection Widening would be collected and conveyed to treatment facilities to provide treatment for 100% of the 2-year storm event. Drainage curbs would be installed near the edge of pavement along the northwest side of the roadway. These drainage curbs would collect and convey flow from the road crown to water quality treatment facilities. The water quality facilities would provide treatment for the design flow volume and bypass higher flows before discharging the runoff into Coos Bay.

Stormwater Management at Kentuck Project Site

Roadway improvements associated with the Kentuck Project, which include elevating and re-paving of East Bay Drive and Golf Course Lane, would result in the addition of new impervious area. The stormwater facilities at the Kentuck Project site would be designed to provide treatment for 100% of the 2-year storm event wherever feasible.

East Bay Drive would sheet flow stormwater runoff to roadside drainage curbs. Once along the curb, water would flow toward cartridge filters which would treat water before discharging the runoff onto rip-rap road base adjacent to the receiving waters in Kentuck Inlet.

Along most of Golf Course Lane, surface water ditches and flow-through bio-infiltration conveyance systems are proposed. In these areas, collected flow that does not fully infiltrate into the underlying well-draining soils would be conveyed to an outfall into the Kentuck Slough. At the north end of Golf Course Road, runoff would be collected in drainage curbs and conveyed to cartridge filters before discharging to Kentuck Slough.

Stormwater Management at Temporary Construction Facilities

Construction laydown areas would be surfaced to a large extent with larger, open-graded aggregate that would allow infiltration; therefore, stormwater from these areas would be self-contained and would infiltrate without the need for outfalls. Impervious surface would not be added at the Pony Village and Myrtlewood Offsite Park & Rides for the JCEP Project Area. Stormwater treatment for temporary facilities is described further in JCEP's Resource Report 2 and the ESCP appended to JCEP's Resource Report 7.

Stormwater Management at APCO Sites

APCO Site 1 (East) would be surfaced with dense-graded gravel and would have existing drainage patterns would be preserved to the maximum extent practical. Stormwater would be treated primarily by vegetated swales and filter strips. Fill placed on APCO Site 2 (West) would be surfaced with native vegetation. Additional storm water controls would be added if necessary. The bridge connecting APCO Site 1 and 2 is in preliminary design. All stormwater run-off from the bridge would be treated prior to discharge to Coos Bay.

As a result of the stormwater management system that would be implemented during Project construction and operation, stormwater runoff and discharges may affect EFH or coastal pelagic, groundfish, and Pacific salmon species under the three FMP groups.

4.2.2.6 Stranding from Ship Wakes

Fish stranding can occur when fish, particularly those with a weak swimming ability, become displaced from shallow waters onto shore by waves generated by the wakes of passing vessels. A description of how fish stranding occurs, various causal factors, and locations in Coos Bay identified as having a potential risk of fish stranding are described in sections 3.5.1.3 and 3.5.4.3. Detailed fish stranding studies involving juvenile salmon and other fish species have been conducted in the Lower Columbia River and provide the primary basis for the following analysis.

Fish stranding typically results in mortality unless subsequent waves return the fish to the water after stranding occurs. A series of interlinked factors act together to produce stranding during vessel passages. These factors may include water surface elevations, with low tides more likely to result in strandings than high tides; beach slope, with strandings more likely on low gradients than high; wake characteristics influenced by vessel speed, size, hull geometry, and depth underwater (draft); and biological factors, such as numbers of small fish with weak swimming ability near the shoreline that tend to be more susceptible to stranding (see section 3.5.4.3).

In the Lower Columbia River, ship wakes produced by deep-draft vessels traveling at speeds greater than the estimates for LNG carriers to be used in the Coos Bay estuary have been observed to cause occasional stranding of juvenile salmon (Pearson et al. 2006). When stranding occurred, however, none was observed as a result of vessels traveling at speeds under 9 knots (10.4 mph). Pearson et al. (2006) also found that salmon larger than 90 mm were generally not susceptible to stranding. The hull geometry of the LNG carriers is such that bow wakes are minimized, especially at the slower speeds of four to six knots that would be typical along most of the transit route through Coos Bay. Therefore, the LNG carriers would be traveling at speeds less than that observed by Pearson et al. (2006) that caused stranding. In models and research conducted by JCEP, wave heights produced by LNG carrier traffic would be less than background levels from existing Coos Bay vessel traffic. Overall, vessel-generated waves would contribute a small proportion of the total waves that occur in the bay when waves caused by natural winds are considered (see models described in section 3.5.1.3). In addition, the LNG carriers would be arriving and leaving the bay at high tide when gently sloping beaches are mostly submerged and less likely to contribute to fish stranding risk.

While more species and life stages would be present year-round in Coos Bay for groundfish than coastal pelagic species, their susceptibility to stranding and loss from vessel wake should not be markedly different for either FMP group than those described below for salmon. Considering that LNG carriers and accompanying tugs would enter and leave the bay at high slack tide and would typically travel at low speeds of 6 knots (6.9 mph) generating wave heights within the normal range of background conditions, Project-related vessel wakes are not expected to adversely affect EFH for the coastal pelagic and groundfish FMPs.

The assessment of potential effects of stranding from Project-related vessel wakes was described for coho salmon in section 3.5.4.3. Based on that analysis, vessel wakes are not expected to adversely affect Pacific salmon EFH in Coos Bay that support both coho and juvenile Chinook salmon. While age 0 Chinook salmon tend to be more susceptible to stranding, partly because of their apparent nearshore distribution, proposed vessel traffic procedures for LNG carriers in Coos Bay that include low travel speeds only at high tide have been found to reduce the stranding loss of even age 0 Chinook salmon in the lower Columbia River to insignificant levels (Hinton and Emmett 1994). The outer mile of the channel, where vessel speed would be the highest, would appear to be a region of greatest potential stranding from large waves generated by vessels. However, the area is also a region of naturally higher waves due to its proximity to the ocean (Wagoner et al. 1990), so ship wake is likely to have a much lower effect than natural conditions relative to frequency and magnitude of shore waves.

Also, although data for Coos Bay are not specifically available, radio-tagging studies of juvenile salmonids in the Columbia River suggest that even age 0 Chinook salmon tended to be more commonly offshore when they are approaching the marine environment near the mouth of the Columbia River (Carter et al. 2009). If this behavior should occur in Coos Bay, it would further reduce the risk of age 0 Chinook salmon from potential stranding by vessel wakes. Overall stranding potential is higher for age 0 Chinook salmon in Coos Bay from vessel wakes than for larger Chinook or coho salmon. Available information suggests stranding of all juvenile salmonids would not be substantial. Project-related vessel wakes, therefore, are not expected to adversely affect Pacific salmon EFH.

4.2.2.7 Ballast Water Exchanges and Exotic, Invasive Species

As described in further detail in section 2.2.6.1.7.1 of JCEP's Resource Report 2 and section 3.1.4.11 in Resource Report 3, LNG carriers must discharge ballast water into the terminal slip when taking on cargo. Each LNG carrier would discharge approximately 9.2 million gallons of ballast water during the loading cycle, which would occur about 120 times per year. While no wastewater would be discharged to the slip, ballast water exchanges (BWEs) could introduce exotic, non-native species into Coos Bay. Should this occur, such organisms may threaten to outcompete and exclude native species thereby affecting the overall health of the estuarine ecosystem. Potential adverse effects of BWEs to the EFH of all three FMP groups would be mitigated by federal mandates that regulate how and where vessels must conduct a BWE before entering U.S. ports. Enforced by the U.S.C.G., these protocols require complete exchange of ballast water in the open sea at least 200 miles from U.S. waters and have been reported to reduce the introduction of exotic and invasive organisms by 88 to 99 percent (NRC 2011). An additional requirement for many marine vessels (depending on size and when constructed) was implemented beginning in 2013. It requires regulated vessels from foreign ports to also treat ballast water, rather than just exchange it with ambient seawater, and to "flush" potential invasive organisms to further reduce the risk of invasive species being discharged at U.S. ports (see section 3.5.1.3 for details of these regulations). Compliance with these regulations by LNG carriers transiting to and from the LNG Terminal, therefore, should effectively reduce risks of introducing exotic, invasive species to the Coos Bay ecosystem.

Ballast water discharges also could affect certain estuarine water quality parameters on a local basis near the point of discharge. For example, salinity could be increased and dissolved oxygen could be reduced as a result of the periodic influx of seawater at the LNG Terminal. While 9.2

million gallons of ballast water would be typically discharged from each LNG carrier, this represents only 0.3 percent of the water passing by the LNG Terminal and only 2.4 percent of the total volume of 374 million gallons in the slip. Relative to the total water volume of Coos Bay, the net change in salinity would be extremely small and discountable. Potential net effects on other water quality parameters, including dissolved oxygen and pH, also would not be notable as described in further detail in section 2.2.6.1.7.1 of JCEP's Resource Report 2 and section 3.1.4.11 in Resource Report 3. Therefore, BWEs may affect but would not adversely affect EFH for the three FMP groups.

4.2.2.8 Entrainment and Impingement

Dredging

During dredging operations, small fish, larvae, fish eggs, and benthic prey species could be entrained. Larger fish with greater swimming ability would be able to actively avoid areas where disturbance from dredging operations occurs. In a review of many maintenance dredge studies through 1998, Reine et al. (1998) concluded that "much of the available evidence suggests that entrainment is not a significant problem for many species of fish and shellfish in many bodies of water that require periodic dredging."

Dredging could affect certain bottom-dwelling fishes, such as Pacific sand lance (*Ammodytes personatus*) which frequently inhabit sands and fine-grain sediments for rest and predator avoidance. Sand lance are an important prey species for many marine mammals, birds, and fishes including marbled murrelet and Pacific salmon. While sand lance could be subject to mortality or injury from proposed dredging, the timing and extent of their presence in lower Coos Bay at the NRI sites has not been confirmed.

Therefore, while entrainment of fish, shellfish, and other benthic species from dredging would be minor, it may adversely affect EFH for the coastal pelagic, groundfish, or Pacific salmon FMP groups. Direct or indirect impacts would be minimized by limiting work to the in-water work window (October 1 to February 15) and by maintaining the dredge cutterhead near the bottom.

Entrainment and Impingement through Vessel Cooling Water Intake at the Terminal Dock

During operation of the LNG Terminal, carriers at the export terminal slip may entrain fish and other marine organisms through the intake of cooling water, which is needed for vessel power plant operations. The potential effects to EFH for three of the FMP fish groups are twofold. The first is direct entrainment or impingement of individuals of these groups, and the second is the entrainment or impingement of pelagic food organisms that these groups feed upon (see section 3.5.4.3 Effects of Proposed Action regarding further details on entrainment and impingement of fish and related food organisms from LNG carrier cooling water intake systems at the Terminal dock).

For purposes of this analysis, typical cooling water flow rates were estimated at 3,200 m^3/hr (845,376 gallons per hour or 14,000 gpm) for 160,000 – 170,000 m^3 carriers with dual fuel diesel electric propulsion. This would result in a total of approximately 22 million gallons of cooling water being recirculated to the slip over a 26-hour loading cycle of LNG cargo. Cooling water flow rates would be 11,000 m^3/hr (2.9 million gallons per hour or 48,430 gallons per minute [gpm]) for 148,000 m^3 carriers with steam turbine propulsion systems. For a 148,000 m^3 carrier, this would total approximately 69.7 million gallons of water being recirvulated during the 24-hour loading cycle of LNG cargo..

The intake ports for engine cooling water would be through the ship's sea chests. A typical LNG carrier has two sea chests. The lower unit is usually located just above the keel of the ship, approximately 10 meters (33 feet) below the water line. It is approximately 3.5 to 4.2 square meters (37.7 to 45.2 square feet) covered by a screen with 4.5 mm (0.18 inch) wide bars, spaced every 24 mm (0.94 inch). The estimated velocity at the opening of the cooling water intake for a steam propulsion system ranges from 2.2 to 4.4 feet per second (ft/sec) (0.66 to 1.3 meters/second), depending on the intake rate of cooling water used. The estimated velocity at the opening of the cooling water intake for a dual propulsion system is approximately 1.3 ft/sec (0.39 meters/second), depending on the intake rate of cooling water used. No additional screening system other than that already employed on the LNG carriers is proposed for water intakes.

NMFS recommends that the approach velocity for screening systems operating where salmonid fry less than 60 mm in length are present should not exceed 0.33 ft/ sec (0.11 meter per second) or 0.8 ft/sec (0.26 meter/second) for larger juvenile salmonids in tidal systems (NMFS 1997c). These guidelines also include other requirements such as sweeping velocity and type and size of openings that are not present on these screens. Based on the anticipated range of velocities at the opening of the cooling water intake, which could reach a maximum of 1.44 ft/sec (0.44 meter/second), fish ranging in size from fry to possibly larger juvenile salmonids (including coho and Chinook salmon) may be entrained or impinged at cooling water intakes if they swim near the intake screens.

In the case of coho salmon, it is anticipated that few in the vicinity of the cooling water intake would be as small as 60 mm (2.4 inches) and subject to potential entrainment or impingement since most coho outmigrate at age 1+ and likely would be greater than 120 mm (4.7 inches) with a strong swimming ability. Similarly, age 1+ Chinook salmon would be of comparable size and swimming ability as coho salmon which also would allow them to be less susceptible to potential entrainment or impingement. Age 0 Chinook, however, which may be present in the Coos Bay estuary during summer, would be more susceptible to entrainment and impingement due to their smaller size. If present in the Terminal slip, many of the juvenile coho and Chinook salmon would, therefore, have sufficient swimming ability to actively avoid being entrained or impinged at cooling water intakes of berthed LNG carriers. Also, since the LNG Terminal slip would be excavated from upland habitat that extends landward from the main channel of Coos Bay, this may reduce the distribution of juvenile salmon in the vicinity of the water intakes of LNG carriers while berthed at the terminal dock. Salmon distribution patterns in Coos Bay are unknown, making it speculative to predict potential losses of fish to cooling water intake entrainment. Studies on the Columbia River, however, found that coho salmon and even smaller Chinook salmon occupied offshore portions of the river channel where the current is greater as they approached the ocean. Should distribution patterns for outmigrating coho and Chinook salmon in Coos Bay also occur primarily in the main channel, this would tend to minimize their potential exposure to cooling water intake entrainment.

Given the LNG carrier water intake and velocity characteristics as previously described, entrainment and impingement would primarily affect zooplankton, larval life stages, and small juvenile fish, since larger organisms could more actively avoid entrainment. Of the EFH species that inhabit Coos Bay, species with planktonic/pelagic eggs and larval life stages include the groundfish species English sole, rex sole, sand sole, starry flounder, lingcod, cabezon, and possibly bocaccio. A recent study found less diverse species near the mouth of the proposed slip (Shanks et al. 2011), but other larval or juvenile fish, including English sole, buffalo sculpin, anchovy, and pipefish, were found to be more abundant. A total of nine fish species were captured near the proposed slip site by Shanks et al. (2011).

Miller and Shanks (2005) collected a total of 35 species of ichthyoplankton in Coos Bay, the most abundant of which were pinpoint gunnel, northern anchovy, rosylip sculpin, Pacific sardine, and surf smelt. These five species consistently comprised more than 70 percent of the total catch. All of these are small, abundant, forage species, and two, sardine and anchovy, are coastal pelagic species. Miller and Shanks (2005) found that at both ocean-dominated and up-estuary sites in Coos Bay, the majority of the catch occurred from October 1 to May 31, although the seasonal difference was less marked within the estuary than it was at the estuary mouth. It can be expected that large numbers of these life stages, which are widely dispersed within the estuary, would be entrained during seasonal periods of high abundance. As noted above, both coho and Chinook salmon juveniles would be present in Coos Bay primarily in late spring and summer.

Should juvenile or larval fish and invertebrates that are small and unable to avoid entrainment occur in the slip area near the LNG carrier's intake screens, it is expected that a high portion would be entrained or impinged, resulting in their mortality. Their loss to the Coos Bay system would diminish their availability as a food source for coastal pelagic, groundfish, or salmon species.

The loss of these organisms from entrainment can be considered in the context of losses from natural mortality in the bay environment. Instantaneous natural mortality rate (per day) can be defined by the function: $M = \ln (N_0/N_t)/-t$, where M is instantaneous mortality rate, and N_0 and N_t are the initial and final abundance of larvae after time t (Rumrill 1990). The comparison of losses of larval food organisms between entrainment and natural mortality was based on the assumption that 100 percent mortality would occur to organisms entrained while water intakes were operating and that all mortality would occur during a single day. Additionally, it was assumed that all pelagic zooplankton in the Project area during water exchange on an average day (i.e., 114.25 million m^3) suffered one day's natural mortality at the rate determined in the literature.

Rumrill (1990) provides estimates of mortality rates for a variety of marine invertebrate larval, and in some cases, through juvenile stages. McGurk (1986) supplies similar information for a variety of larval stages of marine fish. These values provide the basis for the comparison of potential Project entrainment loss to that from natural mortality. Average loss of organisms from entrainment during one LNG carrier loading event would be low, ranging from 0.4 to 0.7percent of the natural morality that would occur in one day. For the lowest literature mortality rate of larval taxa among those reported, daily entrainment loss would be much higher, ranging from 0.7 to 1.8 percent, depending on what water volume was used during one vessel loading cycle and which taxa group data are used. These values, therefore, are conservative estimates when compared to natural mortality that would occur in the Coos Bay system overall, because entrainment would not occur daily, whereas natural mortality would.

While the loss from entrainment of marine fish, including groundfish, coastal pelagic fish, and their prey resources relative to natural mortalities in Coos Bay may be minor, it may adversely affect the supply of food resources to coastal pelagic, groundfish, and Pacific salmon. Further details of how entrainment may affect smaller organisms (e.g., zooplankton and larval fish) are presented in section 3.5.4.3.

4.2.2.9 Temperature Effects in the Marine Slip from LNG Carrier at LNG Terminal

Moderate to large temperature increases have the potential to reduce fish and invertebrate growth, reproductive success, and, if high enough, cause direct mortality. LNG carriers at berth in the LNG Terminal slip have the potential to both warm the water temperature while discharging engine cooling water and to cool the water temperature while loading LNG cargo. Plume modeling was conducted by JCEP to evaluate the three-dimensional thermal character of engine cooling water discharges in the terminal slip from LNG carriers propelled by either steam or dual fuel diesel-electric systems. The model discharge temperatures ranged from 10 to 20.8 °C. The model predicted, three-dimensionally, the distances that engine-heated discharges would attenuate from the LNG carrier discharge portal (i.e., sea chest) to a near-ambient temperature of 0.3°C (0.54°F), the Regulatory Mixing Zone (RMZ). The RMZ is defined as the distance at which water quality standards may be exceeded as long as acutely toxic conditions are prevented and fish habitat and other uses are protected.

Model results showed that, for peak summer ambient flow conditions, water temperatures in the slip that were subject to engine cooling water discharges from steam propulsion carriers would not exceed the thermal RMZ beyond 79.2 feet and 22.1 feet in longitudinal and transverse directions, respectively, with a vertical rise of 12.1 feet. For dual fuel diesel-electric carriers discharging engine cooling water under stratified winter temperature conditions, the RMZ was predicted to extend up to 36.5 feet and 6.9 feet in longitudinal and transverse directions, respectively, with a vertical rise of 1.3 feet. Such temperature differentials would decrease further at greater distances from the point of discharge.

Based on the total estimated slip volume, this would result in an average water temperature increase within the entire slip during a one day vessel loading event that would range from 0.03 to 0.06°F (0.02 to 0.03°C). The water temperature in the slip would be further cooled by contact with the hull of an LNG carrier since loading liquefied gas with a temperature of -260°F (-162°C) would result in the absorption of heat from the water. It was estimated that the hull would absorb an equivalent of 20 percent of the total quantity of heat gained to the slip (see JCEP's Resource Report 2). The elevated temperature of water discharges from engine cooling, therefore, would be ameliorated by the cold hull of the loading LNG carrier, the total volume of water in the slip, and tidal exchanges.

As a result, water in the LNG Terminal slip would be subject to negligible, localized temperature increases during carrier loadings that would not adversely affect EFH of the coastal pelagic, groundfish, or Pacific salmon FMP groups.

4.2.2.10 Operational Lighting

Localized changes in light regime have been shown to affect fish species behavior in a variety of ways (see discussion in sections 3.5.1.3 and 3.5.4.3). As described in further detail in section 1.2.1.4, lighting at the LNG Terminal would likely include a mixture of low-power fluorescent lighting and higher intensity lighting for operations and maintenance, safety, and security. Lighting would primarily be located on shore, in and adjacent to the slip. When an LNG carrier is not in the berth, lighting would be reduced to that required for security. It would be focused upon the structures and not along the water, so as to serve as an attractant or deterrent to fish species. When an LNG carrier is at the berth, it would physically block light from the slip waters and, due to its proximity to the slip wall, would block the fish from getting too close to the lighting on the berth. Lighting would be similar to that already in place at other Coos Bay facilities.

Lighting on the tug dock would be low intensity sufficient for safety and for personnel movements on the trestle out to the tug berth and along the berth itself. The reduced lighting levels near the water would lessen or eliminate any behavioral effects to fish in the Project vicinity. The final details of the lighting design would be determined through consultation with resource agencies, including NMFS and ODFW, in order to minimize potential adverse effects on fish and wildlife resources.

Considering the limited distribution of light that would occur at the LNG Terminal and tug dock areas, mitigation measures to be implemented to reduce light intensity, the availability of ample deep water adjacent to these areas where fish could avoid lights, and based on additional measures to be developed during final design to further minimize light on the water, lighting may affect but would not likely adversely affect EFH of coastal pelagic, groundfish, and Pacific salmon species.

4.2.2.11 Acoustic Effects from Construction and Operation

Underwater noise may affect fish by disturbing their behavior or causing injury or mortality. Effects of noise on aquatic species in Coos Bay from Project-related construction, operation, and maintenance activities were previously discussed for green sturgeon and coastal coho salmon in sections 3.5.1.3 and 3.5.4.3, respectively. Underwater noise would be generated from:

- installation of the sheet pile bulkhead at the LNG berth,
- installation of piles to support the LNG berth, tugboat dock, and temporary dredging pipelines,
- Initial excavation and dredging of the LNG Terminal slip and access channel, and Navigation Reliability Improvements;
- dredging of the eelgrass mitigation site and entrance to the Kentuck Project,
- LNG carrier transit in Coos Bay, and
- general operations at the LNG Terminal.

Individually or combined, these activities would generate underwater sound pressure levels that could elicit behavioral responses in fish and other aquatic organisms.

As discussed in the main BA criteria, dB levels ranging from over 206 dB down to 183 dB can cause adverse effects to fish (Fisheries Hydroacoustic Working Group 2008). Underwater noise may be generated by driving piles on land (dry piles) since some noise propagates through ground and sediments (especially through harder substrates such as rock and clay) and may transfer to the water column somewhere else (known as sound flanking). Wladichuk et al. (2018) modeled potential impacts of land-based pile driving on fish using both current guidelines (FHWG 2008) and new proposed guidelines (Popper et al. 2014). This study found that injury to fish from peak sound pressure levels (206 dB in current guidelines) would occur up to 37 meters from the face of the MOF. Also, this study predicted that injury to both small (less than 2 grams) and large (greater than or equal to 2 grams) fish from cumulative sound exposure levels (183 and 187 dB respectively under current guidelines) would occur up to 1,723 meters from the shoreline. Figure 3.5.1-2 shows the modeled extent of this potential zone of injury in the project area from land-based pile driving at the MOF face.

Based on the results of Wladichuk et al. 2018, installation of land-based piles would increase potential exposure of fish to underwater noise in an area encompassing the navigation channel from the MOF across the bay to the airport and southwest to the vicinity of Southport Lumber yard. These noise thresholds could be reached during pile driving of the 8 mooring bollards at the MOF that would take approximately 14 days to install. Individual fish occurring in this area during pile driving could experience physiological effects sufficient to cause injury. Land-based pile driving at the MOF shown to generate injury-level in-water noise would be limited to the approved in-water work window, which is October 1 through February 15 to minimize risk of physical injury or disturbance to individual Oregon Coast coho and other species in the three fish management groups that may occur in the Project vicinity during construction.

A key source of underwater noise from Project operations is associated with LNG carrier transits. LNG carriers would generate the greatest magnitude of noise relative to any vessels operating in the action area. Peak noise values within one meter (three feet) from an LNG carrier hull would likely be 182 ± 2 Db, although this value is based on LNG carriers in open-ocean transit. Peak noise values would likely be less in Coos Bay where vessels would be traveling at a much slower speeds. As a result, no adverse effects to fish in the estuary would result from LNG carrier transit.

Dredging operations also can produce high underwater noise levels. Fischer (2004) noted dredging source dB levels of 172 and 185 dB at one meter (three feet) from the dredge head. While the upper levels would exceed the lowest effects criteria (the threshold where effects occur to small fish less than two grams), dredging would be constrained to the in-water work period when the abundance of juvenile salmonids in the bay is low. Additionally, it is expected fish would avoid areas within one meter (three feet) of the dredge head. As a result, underwater noise levels from dredging would be minor but would not adversely affect EFH of all three fish management groups.

4.2.2.12 Habitat Effects –Slip, Access Channel, and Pile Dike Rock Apron

Prey species important to local EFH fish species rely on many of the same habitat conditions as the EFH fish species themselves. The food web components, including phytoplankton, zooplankton, detritus, epiphyton, and submerged aquatic vegetation (e.g., eelgrass, macrophytic algae), are all important in supplying the habitat and food base for EFH species within Coos Bay. Eelgrass is one of the more important components that provides refuge for a variety of fish, such as salmon and anchovy. Such refuge may lower predation and allow more opportunity for foraging. The protective structure attribute of eelgrass is primarily for smaller organisms and juvenile life history stages of fish. For example, submerged aquatic grasses are important habitat for small prey species of adult lingcod (in Appendix B-2 of PFMC 2008). Submerged grass meadows provide cover and food for a large number of organisms, including burrowing, bottom-dwelling invertebrates; diatoms and algae; herring that deposit eggs clusters on leaves; tiny crustaceans and fish that hide and feed among the blades; larger fish, and crabs that forage in the meadows at various tides. Previous studies (Akins and Jefferson 1973) have reported that Coos Bay has 1,400 acres of lower intertidal and shallow subtidal flats covered by eelgrass meadows.

Other inter- and sub-tidal habitat components also supply food resources or provide refuge for a variety fish resources, so that modification, disruptions, or loss of these conditions, especially eelgrass, may have adverse effects on EFH resources.

Construction of the LNG Terminal facilities, including the Slip, access channel, pile dike rock apron, MOF, the four sites where Navigation Reliability Improvements would be conducted, Trans Pacific Parkway/ Hwy 101 Intersection Widening, and temporary impact areas, would affect existing estuarine habitat. Where dredging is involved, this would affect about 14.76 acres of intertidal to shallow subtidal habitat, 1.9 acres of eelgrass habitat, and 0.06 acres of salt marsh. These areas would be converted to primarily deep subtidal habitat by dredging the Slip, access channel, and MOF (see table 3.5.1-4 in section 3.5.1.3). About 36.7 acres of upland habitat would be converted to open water, primarily deep subtidal habitat down to -45 feet (NAVD88). In addition, about 2.3 acres of intertidal, eelgrass, and subtidal habitat, would be covered by a three-foot thick layer of rock. This would be accomplished by placing 6,500 cubic yards of well graded 6-inch to 22-inch angular stone with a median size of 14 inches over a 50-foot wide by 1,100 foot long area. The purpose of the new rock apron is to prevent anticipated slope migration near pile dike 7.3 after the access channel is dredged.

Benthic and epibenthic invertebrates that presently inhabit shallow intertidal and subtidal regions within the boundaries of the proposed access channel dredging area would be removed from the bay with the dredged materials are transferred to upland disposal sites. Ghost shrimp and sand shrimp (adults, juveniles, and larvae), amphipods, clams, Dungeness crab, and various demersal (bottom) fish species are important prey for many other fish species, including salmon and groundfish. As a result, the available food supply for EFH fish in the bay would be reduced until the affected benthic and epibenthic communities are re-established within the dredged areas. The resulting deeper habitat would have a character that is less diverse and less productive as benthic food sources.

Many groundfish species are known to occur within the estuary, either seasonally or year-round. Project activities related to dredging are likely to have the greatest impact on flatfish residents of the lower bay, including English sole and starry flounder. Access channel dredging would convert 14.76 acres of shallow water habitat to deepwater habitat. Juvenile English sole and starry flounder are typically found in shallow nearshore waters in estuarine environments. Therefore, the conversion from shallow water to deep water habitat would represent a reduction in habitat quality and quantity over existing conditions. Flatfish and other demersal species are expected to return to the area after dredging is completed. Most rockfish species in the lower bay prefer rocky reef habitat and do not commonly utilize sand/mud substrates that would be affected by dredging. The new rock apron at pile dike 7.3 would provide additional habitat for rockfish, ling cod, cabazon, and bocaccio. Juvenile lingcod and adult cabazon and bocaccio are known to occasionally utilize sandy flats habitat and would experience some loss of such habitat.

However, the sandy habitats that would be removed by dredging are common within the estuary. It is anticipated that groundfish species would be able to relocate to nearby suitable habitats.

While short-term loss of important eelgrass habitat is of concern, it would be a small portion of the total Coos Bay area eelgrass beds of 1,400 acres. Also, the loss of the 2.08 acres of eelgrass by construction and operation of the LNG Terminal would be mitigated at a proposed off-site eelgrass mitigation area south of the west end of the Southwest Oregon Regional Airport where approximately 6 acres of new eelgrass habitat would be created. The 3:1 mitigation ratio would offer a net long-term gain in eelgrass habitat (see appendix O/Compensatory Wetland Mitigation Plan). The interim loss of unvegetated mud flat (intertidal and shallow subtidal habitats) would be restored at (see appendix O/Compensatory Wetland Mitigation Plan) Kentuck Project.

LNG carrier transits through the Coos Bay channel combined with tugboat turning operations would disturb small areas of the channel bottom during arrival and departure. This would cause some short-term loss and/or displacement of organisms. Large organisms (crabs/shrimp) would be able to move and return, while some benthic organisms would have a more extended loss. Overall, an undefined loss of benthic organisms may result from LNG carrier propwash scour during each trip near the slip approach. The magnitude of such loss, however, likely would be small and less than what currently results from bottom disturbance by existing large deep-draft vessel trips. Modeling results have indicated that bottom velocities and related channel disturbance from existing deep-draft vessels would be slightly greater than what would occur from slower traveling LNG carriers (see JCEP's Resource Report 2).

While studies in Coos Bay have indicated that benthic communities inhabiting mud substrates recovered to pre-dredging conditions in four weeks (McCauley et al. 1977), recovery in estuarine channel muds has been reported to typically require six to eight months (Newell et al. 1998). McCabe et al. (1997, 1998) noted benthic organism recovery in the lower Columbia River occurred in three months. Because of the large quantity of proposed dredging, including areas outside the FNC that have a more varied substrate, it may take longer than four weeks to recover the affected habitat relative to what may be more typical as a result of Coos Bay dredging. A short-term loss in bottom habitat, likely less than one year, would affect benthic communities and potential food resources for the EFH fish species in the three FMP groups. Proposed mitigation, including restoration of the Kentuck site and development of new eelgrass habitat, is expected to result in long-term net benefits to EFH. Therefore, while temporary adverse effects to EFH fish species in the three FMP groups may occur, long-term effects and not expected.

4.2.2.13 Habitat Effects –Pipeline HDD

As discussed above, inadvertent return during any of the three HDDs (two across Coos Bay, one across the Coos River) could occur although available information suggests the likelihood is remote. Bentonite by itself is a non-toxic drilling mud (Breteler et al. 1985; Hartman and Martin 1984; Sprague and Logan 1979) although according to Reid and Anderson (1998), the toxicity of bentonite (sodium montmorillonite) in fresh water ranges from 5,000 to 19,000 ppm (mg/liter) based on 96-hour tests for LC50 (the concentration at which 50 percent of the test population dies after 95 hours of exposure) on rainbow trout. The toxicity classifications based on LC50 values ranged from "slightly toxic" to "practically non-toxic" (Reid and Anderson, 1998). In other tests, toxicities to lake whitefish and rainbow trout demonstrated threshold concentrations of 16,613 and 49,838 ppm (mg/liter), respectively (Reid and Anderson, 1998). LC50 concentrations > 10,000 ppm would be considered "practically non-toxic" (Reid and Anderson 1998).

Bentonite, as with any fine particulate material, can interfere with oxygen exchange by the gills of aquatic organisms (EPA 1986). The degree of interference generally increases with water temperature (Horkel and Pearson 1976). Impacts would be localized and would normally be limited to individual fish in the immediate vicinity of the inadvertent return. The majority of highly mobile aquatic organisms, such as fish, would be able to avoid or move away from turbidity spots and plumes (Reid and Anderson 1999). Short-term pulses of suspended sediments (sharp increases within an hour) disrupt the feeding behavior and dominance hierarchies of juvenile coho salmon and elicit alarm reactions that may cause fish to relocate downstream to undisturbed areas (Wilber and Clarke 2001; Berg and Northcote 1985). Other less mobile or immobile organisms, such as clams, mussels and other macroinvertebrates, would incur direct mortality (Wilber and Clarke 2001). Bentonite can smother macroinvertebrates and adversely affect filter-feeders (Falk and Lawrence 1973 in Hair et al. 2002 and Land 1974 in Cameron et al. 2002). Bentonite can also exacerbate or enhance the effects of toxic compounds to fish and aquatic invertebrates if those compounds are present in aquatic habitats (Hartman and Martin 1984). Similar to other fine-grained particulates, bentonite in flowing water is more likely to remain in suspension longer than in standing water. Consequently, effects to coho salmon by a release of bentonite into a waterbody would ultimately depend on volume of the release, volume of water present, and current. Coho salmon inhabiting larger waterbodies with swift currents would be less affected by a given volume of bentonite than those inhabiting small waterbodies with no current. Considering the small size of the area, and short duration of effects to the benthic community, the loss of potential food resources for EFH species, including salmon and groundfish such as starry flounder, would be small.

4.2.2.14 Shading Effects

Shading from over-water structures reduces the amount of light available to phytoplankton and aquatic macrophytes. These may also be areas where predators can hide. The estuarine habitat where shading would occur would involve an industrial area of the slip excavated from upland habitat that would generally provide poor habitat conditions (deep, riprap) and was not originally estuarine habitat. This is a small area with facilities as described in section 3.5.1.3. Consequently, shading impacts to EFH, such as benthic production and potential increased predations, would be small and unsubstantial.

Consequently, shading impacts to EFH, such as benthic production and potential increased predations, would be small and unsubstantial.

4.2.2.15 Aquatic Nuisance Species in Coos Bay Estuary

Invasive species have the potential to modify the food base and induce other ecological modifications in the estuarine area of Coos Bay. Another potential source of invasive species, other than LNG carrier ballast water, is the transfer of organisms between water bodies by construction equipment used in the water, or through other water transfer actions. PCGP has stated that it would not obtain hydrostatic test water from either Coos Bay or the Coos River, in order to prevent the spread of NAS from the estuary to inland watersheds. PCGP currently has procedures in their *Hydrostatic Testing Plan* (see appendix U) to reduce or eliminate the spread of invasive species. Indirect adverse effects to EFH for the three FMP groups are not anticipated to occur, considering the proposed reasonable actions that would be taken to prevent introduction.

4.2.3 Riverine Analysis Area

The riverine analysis area includes all freshwater sources that may be affected by Project actions and that may affect waters historically accessible to salmon. This area primarily includes waters crossed or adjacent to the freshwater portion of the Pipeline, as reported in sections 3.5.3 and 3.5.4 for the two ESA-listed coho salmon ESUs. Effects to EFH in this area would be associated with pipeline construction and operation, associated reconstructed, temporary and permanent road construction, and ancillary facility construction (e.g., meter stations, storage yards).

Effects to coho salmon and their habitat have been addressed in detail in section 3.5.3.3 for the SONCC coho salmon ESU and in section 3.5.4.3 for the Oregon Coast coho salmon ESU. While there are some differences of life history timing among the other Pacific salmon species in the riverine analysis area, Chinook salmon and their distribution are generally a subset of that covered for these two coho salmon. The types of effects to Chinook salmon EFH from Project actions would be mostly the same as for coho salmon. Effects as described in those sections are descriptive of the effects to Pacific salmon EFH in the riverine analysis area, and descriptions below are mostly summaries of the main BA analysis.

4.2.3.1 Acoustic Shock and Underwater Noise

There are many crossings within the range of Pacific salmon where shallow bedrock may occur and where blasting and/or mounted impact hammers may need to be used to construct a trench through the bedrock substrates. Explosives detonated near water produce shock waves that can be lethal to fish, eggs, and larvae by rupturing swim bladders and addling egg sacs (British Columbia Ministry of Transportation 2000). PCGP may opt a variety of actions to reduce the effects to fish, including bubble/air curtains, scare noise to move fish away from the site, and fish removal from the affected area. These and other actions are included in the *Blasting Plan*, and fish removal from the area would be done under the *Fish Salvage Plan* (see section 4.3.3 below); both plans are intended to reduce adverse effects to fish. Prior to any blasting, proper permits would be obtained and agencies notified as required by the associated permits.

Noise, like that generated from an impact hammer at bedrock stream crossings, can also have adverse effects to Pacific salmon. The noise produced by the impact hammer in air would be equivalent to about 182 dB re: 1 µPa @ 1 meter (3 feet) in water. This is near the lower level considered to be directly harmful to fish. Sound levels less than this (e.g., 90 dB) are at the hearing threshold of some salmonids, so some avoidance may occur at lesser sound levels. With the fish removal practices in place, Pacific salmon would not be in the zone of direct impact of such sound. However, associated salvage of fish remaining in isolated crossing areas where blasting or impact hammers are used would likely result in some mortality.

Overall, considering plans and procedures that are in place, and the limited need for blasting or air hammer use, direct impacts to Pacific salmon and their EFH from blasting or impact hammer use would not occur, although associated fish salvage operations would have adverse effects.

4.2.3.2 Suspended Sediment Effects from Stream Crossings

Four crossing methods (dry open cut, direct pipe, HDD, and diverted open cut) would be used for stream crossings along the route where Pacific salmon would occur (see sections 3.5.3.3 and 3.5.4.3). All but four of the stream crossings in the range of the Pacific salmon would be dry open cut (either dam-and-pump or flume). Dry crossing methods, including diverted open cut, would result in minimal impacts but would include temporary increases in suspended sediments in restricted areas. Direct pipe and HDDs would be installed without in-water work, and would not directly affect the aquatic environment and associated species—except in the case of an inadvertent return during an HDD crossing, which could affect stream suspended sediment levels.

Salmonids exposed to moderate to high levels of suspended sediment for extended periods could be adversely affected. At high levels, turbidity directly affects survival and growth of salmonids and other species, interferes with gill function, and adversely affects substrate for egg development (Bash et al. 2001). Turbidity can also reduce macrophyte cover over the long-term by limiting photosynthesis (Goldsborough and Kemp 1988), as well as adversely affecting fish vision, which is a requisite for social interactions (Berg and Northcote 1985), feeding (Vogel and Beauchamp 1999; Gregory and Northcote 1993), and predator avoidance (Meager et al. 2006; Miner and Stein 1996).

Suspended Sediment – Dry Open Cut

Estimated effects on salmonids from suspended sediment were based on models of concentrations at crossings and on literature detailing what effects occurred at other typical crossing types. Newcombe and Jensen (1996) compiled research from many sources that demonstrate effects to anadromous and resident salmonids by various levels of suspended sediment and exposure over time. The model developed in Newcombe and Jensen (1996) is considered reasonable for assessing effects to listed coho salmon, and the results are considered suitable for assessing effects to Pacific salmon EFH. The details of the model are in section 3.5.

Output from each model provides SEV scores. Values range from 0 to 14, where an SEV of 0 indicates no effects, an SEV between 1 and 3 indicates behavioral effects, an SEV from 4 to 8 indicates sublethal effects, and an SEV from 9 through 14 indicates lethal and paralethal effects (see Table 1 in Newcombe and Jensen 1996).

Modeled estimates of the effects of suspended sediment to coho salmon resources from pipeline installation across streams would remain mostly low to moderate (SEV 3 to 5) in the short-term. These effects to coho salmon would likely include short-term avoidance, short-term reduction in feeding, and minor physiological stress. Based on modeled results, effects would be similar among most fifth-field watersheds where salmon are present along the route. A few modeled effects would have higher impact levels if any of the crossing methods have failures.

Overall, the result for either dry crossing method would be that suspended sediment generated during crossing construction would cause at least some short-term adverse effects, primarily avoidance, short-term feeding reduction, and likely some minor stress. No long-term adverse effect would likely occur to Pacific salmon or their EFH unless some major failure occurred during construction.

Following review of an earlier draft, FERC (2018) requested an analysis of any coho salmon or EFH stream that is not directly crossed by the Pipeline, but has a tributary that would be crossed that could have an effect on this fish stream from the tributary stream's downstream sediment distribution based on the severity of ill effects value indicated. However, addressing this comment requires a different methodology than used in the nearest neighbor analysis provided for SONCC coho in section 3.5.3.3 and Oregon Coast coho in section 3.5.4.3. In that analysis, NMFS assumed that the nearest neighbor distance was equivalent to the downstream confluence of the two. However, FERC's request requires measuring the actual distance from the point where the tributary is crossed to the confluence with coho/EFH and would include most of the streams crossed in appendix M/table M-1. For example: a Tributary to Trail Creek at MP 119.84 is 824 meters from the confluence with Trail Creek which provides Pacific salmon EFH. The tributary is an intermittent stream, 2 feet wide crossed by dry open-cut (flume) requiring 2 hours of instream work. Using the appropriate regression model in table 3.5.3-3, at 824 m downstream, the TSS = 14.2 mg/l which yields SEV = 3 (using the Newcombe and Jensen [1996] Model #1 for juvenile and adult salmonids). Thus at the confluence, SEV in the Tributary = 3, but that does not equate to SEV = 3 in Trail creek because the TSS concentration entering from the Tributary would be diluted from 14.2 mg/l. SEV in Trail Creek EFH would be <3. Similar estimates were made for all tributaries (except for ditches) to streams with EFH, either Known or Assumed to be occupied by coho, and are included in table 4.2.3-1. Effects to waterbodies crossed that support or are assumed to support SONCC coho and Oregon Coast coho and effects by crossing nearest neighbor streams are provided in table 3.5.3-23 (SONCC coho) and table 3.5.4-28 (Oregon Coast coho) and are not included in table 4.2.3-1, below.

Every waterbody crossed during construction is eventually connected to an EFH stream. However, downstream distances to an EFH stream may be too large to warrant any meaningful evaluation such as provided in table 4.2.3-1. That was the case for all waterbodies crossed in the Upper Cow Creek watershed. In table 4.2.3-1, risks from downstream TSS by crossing any stream with a bedrock substrate are considered "None-Low" because fine sediment (silt and clay) would not be mobilized in the water column; risks of downstream TSS crossing intermittent streams are considered "None-Low" because those streams would likely be dry during the in-stream construction period (ODFW 2008); risks from downstream TSS by crossing perennial streams are considered "Moderate-High" because flowing water would be present at the time of construction. The highest risk for SEV = 5 (causing minor physiological stress) would occur at the confluence of a tributary to Big Creek (Middle Fork Coquille River watershed), assumed to support coho and EFH because it is occupied by steelhead. All other SEV values at a tributary's confluence to an EFH stream are SEV ≤ 4. However, the estimated TSS concentration at any tributary confluence would be diluted by greater flow rates and water volumes in larger EFH streams and therefore the estimated SEV in the EFH stream would be considerably less than at the confluence.

a/ Only waterbodies crossed by dry open-cut construction (fluming or dam-and-pump at streams with bedrock substrates) are included.
b/ OHM – ordinary highwater mark provided in wetland and waterbody delineation surveys. OHM is assumed to be the width of the waterbody during instream crossing period.
c/ These streams are either known to support coho with information from ODFW (2017f) or assumed to support coho if steelhead occur.
d/ Distance measured digitally on USGS topographic base maps with Forest Practices statewide hydrography (ODF 2018) superimposed.
e/ Instream durations based on stream widths, see table 3.5.3-21 (SONCC coho) and table 3.5.4-26 (Oregon Coast coho).
f/ Estimated TSS concentrations derived from watershed-specific equations in table 3.5.3-20 (SONCC coho) and table 3.5.4-25 (Oregon Coast coho) with relationships between distance downstream (x) and TSS concentration (y) for fluming and dam-and-pump construction.
g/ SEV score at the confluence of EFH stream and tributary crossed during construction derived by applying duration of exposure (hours) and TSS concentration (mg/l) in Newcombe and Jensen (1996) Model 1 for juvenile and adult salmonids.
h/ Risks from downstream TSS by crossing all streams with bedrock substrate are considered None to Low; risks of downstream TSS crossing intermittent streams are considered None to Low; risks from downstream TSS by crossing perennial streams are considered Moderate to High.

Suspended Sediment – Other Crossing Methods

The other crossing methods include two HDDs (including the Coos River, discussed above, and the Rogue River), one diverted open cut, and one DP (both in the South Umpqua River). These methods would all be used on large streams containing both coho and Chinook salmon. Considering the low likelihood of elevated sediment from these crossings, the potential for rapid dilution of any excess sediment discharge (e.g., HDD inadvertent return) because of substantial flow in these streams and construction and contingency plans in place (e.g., Drilling Fluid Contingency Plan for Horizontal Directional Drilling Operations), and other factors noted in sections 3.5.3.3 (SONCC coho) and 3.5.4.3 (Oregon Coast coho), no adverse effects to Pacific salmon EFH from elevated levels of suspended sediment would occur at these crossings.

4.2.3.3 Movement Blockage

Dry open-cut construction is expected to cause short-term inhibition of upstream movement by adult salmon, as well as within-stream movements of juvenile coho and Chinook salmon. Restrictions on migration could occur from short-term elevation of suspended sediment and the method of water diversion around the stream crossing area. The fluming process is expected to require from 36 to 96 hours of in-stream work, and dam-and-pump construction is expected to require between 20 and 56 hours of in-stream work. Short-term elevation of turbidity could delay upstream movements during this period. Flume sites would allow some upstream and downstream movement, but complete movement restrictions would occur at dam-and-pump sites. Overall, the levels of suspended sediment and physical structures would not cause lengthy delays to adult coho or Chinook salmon migrating upstream, resulting in unsubstantial effects to the EFH of Pacific salmon.

4.2.3.4 Entrainment and Entrapment

Waterbody crossings using the "dry" crossing methods (i.e., flume or dam-and-pump) may result in some rearing coho and Chinook salmon juveniles being entrapped in streams during fluming or dam-and-pump installations. For typical crossings, once streamflow is diverted through the flume pipe, but before trenching begins, fish trapped in any water remaining in the work area between the dams would be removed and released (salvaged) using the *Fish Salvage Plan* (see appendix T). Salvage methods, which all have a risk of fish injury or mortality, could include seining, dip netting, and electrofishing (see section 4.3.3). Fish not removed successfully could be entrained or impinged in water removal pumps. Overall, some juvenile coho and Chinook salmon are likely to suffer injury or mortality, but with the implementation of Project conservation measures, the numbers would be slight, resulting in a short-term adverse effect to the EFH of Pacific salmon.

4.2.3.5 Riparian Vegetation Removal and Modification

Aquatic resources associated with the EFH of Pacific salmon could be affected as a result of removal of vegetation and habitat at the waterbody crossing sites, as required for pipeline construction and associated facilities. In areas of riparian vegetation, PCGP would narrow to a 75-foot-wide construction right-of-way at waterbody crossings, and maintain a setback between waterbody banks and TEWAs in forested areas. As discussed in sections 3.5.3.3 (SONCC coho) and 3.5.4.3 (Oregon Coast coho), various actions would be taken to reduce the loss of vegetation and restore the habitat. The ECRP (see appendix F) describes the procedures that would be implemented to minimize erosion and enhance revegetation success for the entire Project.

Restricting the low-growth vegetation area to a small portion of the total riparian right-of-way clearing would allow much of ecological function of the riparian conditions to continue. This would limit the overall long-term impacts from loss of riparian habitat to a small portion of each stream crossed, reducing future negative effects to Pacific salmon resources. Some limited intermediate-term adverse effects to salmon habitat function would remain, primarily relating to LWD reduction. The effects of riparian vegetation removal on water temperature and LWD are presented below.

Water Temperature

Clearing the right-of-way would remove shading vegetation from uplands and riparian areas, exposing the land and water to increased sunlight, potentially resulting in direct increases in water temperatures. Additionally, indirect increases in stream water temperatures may occur as water flows over the warmer land surface and eventually reaches the waterbody (Beschta and Taylor 1988). The details of the literature and model assessments of likely temperature changes and effects to EFH are presented in sections 3.5.3.3 and 3.5.4.3. The main conclusion is that water temperature changes to fish-bearing streams from clearing would be slight, possibly a few tenths of a degree Celsius increase. These increases would not be biologically significant, and would result in no substantial adverse effect to Pacific salmon EFH.

Large Woody Debris

A potential effect that would result from forest clearing at waterbody pipeline crossings is the reduction of LWD in streams and on adjacent uplands (Harmon et al. 1986; Sedell et al. 1988). Existing conditions associated with riparian vegetation within all fifth-field watersheds in the range of the Oregon Coast and SONCC coho salmon ESUs are generally undesirable. Streams in these watersheds are generally deficient in LWD. Though most of crossings have less than mature sources of LWD, the Project would remove some of these sources, primarily by clearing the 75-foot-wide right-of-way and maintaining a portion of this area in less than mature forest conditions. PCGP has proposed to use on-site mitigation for impacts to waterbodies by installing LWD at appropriate agency and landowner-approved areas within the construction right-of-way across certain waterbodies (see section 4.3.3). Long-term losses of LWD input would largely be mitigated through riparian replanting of conifers in the right-of-way, as discussed at the beginning of section 4.2.3.5. While there may be some reduction in total stream LWD between the short and long-term, the amount would be relatively small considering the total area that could be affected (most of a 75-foot channel), and the mitigation and enhancements that would be implemented (see section 4.3.3), so that LWD changes would result in minor intermediate-term adverse effects to the EFH habitat of Pacific salmon.

4.2.3.6 Streambank Erosion and Streambed Stability

The clearing and grading of the right-of-way during construction could increase erosion along streambanks, resulting in higher turbidity levels in the waterbodies crossed. Alteration of the natural drainage ways or compaction of soils by heavy equipment near streambanks during construction may accelerate erosion of the banks, increase runoff, and induce the transportation of sediments into waterbodies. Stream crossings that are unstable can ultimately adversely affect aquatic resources through loss of local habitat, and impacts to downstream habitat from the addition of highly unstable sediment. This increases the recovery time of the specific site to stable conditions.

Because of FWS concerns for potential adverse effects to bank and bed stability, PCGP has conducted an initial assessment of crossing conditions of all streams suitable for analysis, based on the FWS risk matrix (GeoEngineers 2017d and 2017e). Based on this analysis, no crossing was rated as having both a high risk of Project impact potential and high risk of stream and site response potential within the range of Pacific salmon. Reassessment of the risk would occur prior to construction. Additionally, PCGP would include additional mitigative actions at the higher risk crossings to help reduce the potential for impacts, including post-construction monitoring of all crossings (see sections 3.5.3.3 and 3.5.4.3). Additional site-specific plans would be developed at selected sites to aid ensuring stream habitat protections. Overall, these actions would reduce potential adverse effects from bank and bed stability to unsubstantial levels for the EFH of Pacific salmon.

4.2.3.7 Aquatic Habitat

There also are potential, indirect effects to aquatic habitat from increased suspended sediment from stream crossings. The most likely effect of suspended sediment increases downstream would increase embeddedness of spawning gravels, with increasing habitat effects closer to the construction location. Considering the estimates of likely suspended sediment levels, some measured change in habitat preference may occur but it would not reach the level of moderate habitat degradation. Where uninterrupted dry open-cut construction occurs, indirect adverse effects to Pacific salmon EFH from crossing-induced suspended sediment are thus not expected.

4.2.3.8 Freshwater Stream Invertebrates

Substrates downstream from in-stream construction sites could be impacted by sediments. Mayflies, caddisflies, and stoneflies prefer large substrate particles in riffles, and are adversely affected by fine sediment deposited in interparticulate spaces (Cordone and Kelley 1961; Waters 1995; Harrison et al. 2007). Fish and benthic macroinvertebrate abundances downstream of pipeline construction sites have been reported as short-term reductions (Reid and Anderson 1999). However, rapid colonization by benthic organisms of disturbed substrate following pipeline construction has been demonstrated in several studies (see section 3.5). Most studies finding effects to benthic resources were from wet open-cut crossings, which have much higher sediment levels (see sections 3.5). Therefore, the overall level of effects of the pipeline crossings on waterbodies, unless crossing sealing failures occur, would be even less than that noted by literature, and would not result in substantial reduction in growth or survival of salmon individuals.

4.2.3.9 Hydrostatic Testing

Water would be required on a one-time basis near the end of construction to hydrostatically test the pipeline. Potential impacts associated with hydrostatic testing include entrainment of fish, reduced downstream flows, impaired downstream uses if test water is withdrawn from surface waters, and erosion, scouring, and a release of chemical additives as a result of test water discharge. PCGP would minimize the potential effects of hydrostatic testing on these watersheds by adhering to the measures in its *Hydrostatic Testing Plan* (see appendix U), including screening intake hoses to prevent the entrainment of fish and other aquatic organisms. Additionally, where water cannot be returned to the original water source, it would be discharged upslope (at least 150 feet from streams with no direct discharge features) to prevent direct water return to the stream. PCGP would obtain all necessary appropriations, withdrawal, and discharge permits through the OWRD. With the implementation of these plans and BMPs, and through obtaining and complying with required permits, adequate measures would be in place to prevent direct or indirect adverse effects to Pacific salmon EFH.

4.2.3.10 Aquatic Nuisance Species

Nonindigenous Aquatic Species (NAS) are aquatic species that degrade aquatic ecosystem function and benefits, in some cases completely altering aquatic systems by displacing native species, degrading water quality, altering trophic dynamics, and restricting beneficial uses (Hanson and Sytsma 2001). Some of the major potential freshwater invasive species are mussels, including the zebra and quagga mussels (*Dreissena polymorpha*, and *Dreissena rostriformis bugenisis*), as well as Chytrid fungus and other species of concern. Management priorities in Oregon concentrate on the species whose current or potential impacts on native species and habitats, and economic and recreational activity in Oregon, are known to be significant (Hanson and Sytsma 2001).

Aquatic nuisance species could potentially be introduced into project area waters by basin transfer through hydrostatic testing waters, or be carried on equipment that is moved from outside of the region or between basins. PCGP has developed BMPs and guidelines to avoid the potential spread of the aquatic invasive species and pathogens of concern (see *Hydrostatic Testing Plan* in appendix U). To prevent the introduction of aquatic nuisance species, PCGP may follow the guidelines of this plan during construction. With the implementation of the details of this Plan and other procedures, introduction of non-native species or movement of species between basins should not occur, resulting in no adverse effects to Pacific salmon EFH.

4.2.3.11 Fuel and Chemical Spills

Fisheries habitats could be adversely affected if petroleum products were accidentally discharged into aquatic environments. Such materials are toxic to algae, invertebrates, and fish. Of the products likely to be present during construction, data compiled from a wide range of sources indicate that diesel fuels and lubricating oils are considerably more toxic to aquatic organisms than other, more volatile products (gasoline) or heavier crude oil (Markarian et al. 1994). Inadvertent spills of fluids used during construction, such as fuels and lubricants, could contaminate wetland soils and vegetation. To minimize the potential for spills and any impacts from such spills, PCGP's SPCCP (see appendix L) would be implemented. In general, hazardous materials, chemicals, fuels, lubricating oils, and concrete-coating activities would be not be stored, nor would refueling operations be conducted within 100 feet (150 feet on BLM and Forest Service lands) of a wetland or waterbody in accordance with FERC's *Procedures* (see appendix C) and the SPCCP (see appendix L), except where no reasonable location is possible and additional containment steps have been taken. The SPCCP would be updated with site-specific information prior to construction. Adherence to these plans and procedures would result in effects to the Pacific salmon EFH that would be unsubstantial.

4.2.3.12 Operation and Maintenance Activities

Once the pipeline is installed, maintenance would include activities such as aerial inspections, gas flow monitoring, visual inspection of surrounding vegetation for signs of leaks, and integrity management, which includes smart pigging to investigate the interior surface of the pipe for any signs of stress cracking, pitting, and other anomalies (see the ECRP in appendix F). All of the proposed maintenance activities would be outlined in the Operations and Maintenance Plan that would be prepared according to operating regulations in DOT 49 CFR Subpart L, Part 192, and would be completed prior to going in-service. These general maintenance activities would require only surface activities and usage of the existing right-of-way, such as insertion of the pig (an internal pipeline cleaning and inspection tool) at one of the pig launching facilities.

Within stream sites, repair work could require isolated flow from the section of pipe that is to be exposed. Impacts would be similar to those discussed above for initial installation, except on a much smaller scale. Repairs that may need to occur outside the fish window period would likely have more site-specific effects to EFH fish resources. Standard BMPs would be followed and needed permits would be obtained to aid in reducing impacts. Very limited effects would occur to riparian areas if repairs were needed, as a portion of the right-of-way would be permanently maintained as largely vegetation free. No vegetation or tree limitations would occur beyond the 30-foot-wide corridor in riparian areas (i.e., up to 100 feet of streams on federal lands, and 25 feet on non-federal lands).

Herbicide Application

Herbicides have the potential to cause toxic effects to different salmonid life stages and to other aquatic species, causing direct impacts if used improperly. However, when herbicides are properly used according to label restrictions and BMPs to control noxious weeds, there is little to no chance of causing injury or mortality to fish or other aquatic organisms.

As discussed in sections 3.5.3.3 (SONCC coho) and 3.5.4.3 (Oregon Coast coho), PCGP would not use herbicides for routine vegetation maintenance, but instead would employ hand and mechanical methods (pulling, mowing, biological, disking, etc.) to prevent the spread of potential weed infestations where feasible, and implement management plans specific to land ownership to ensure proper use and to prevent entry of herbicides into streams. The BMPs would minimize the potential spread of invasive species and minimize the potential adverse effects of control treatments. Herbicides would not be applied by aerial or broadcast spraying. With the implementation of the BMPs, elimination of use of herbicides near streams, and only selective use of these chemicals in areas away from streams, meaningful negative effects to Pacific salmon EFH from herbicides would be unlikely to occur.

4.3 CONSERVATION AND MITIGATION MEASURES

All avoidance, minimization, BMP, and mitigative actions that may reduce, avoid, eliminate, or otherwise offset adverse effects to EFH are considered here as EFH conservation measures for the Project. The conservation and mitigative measures described in the main BA section 3.5 and incorporated in to the text descriptions of the potential effects for the four ESA listed fish species would also apply to the four FMP fish EFHs. These ESA fish conservation measures address the same concern of potential Project-induced adverse effects to habitat for the four FMP fish groups, because portions of the four ESA fish habitat uses overlap in the three Project analysis areas: marine, estuarine, and riverine. Conservation measures for the marine would benefit the EFH of all four FMP fish species; the conservation measures used in the estuarine analysis area would benefit all but the highly migratory EFH; and the measures applied in the riverine analysis area would aid Pacific salmon EFH. While the details of the conservation measures are provided under each of the four ESA-listed species, a summary of most that apply by each of the three analysis areas is provided below. Not all actions that may reduce adverse effects in these analysis areas are listed.

4.3.1 Marine Conservation Measures – All Four FMP EFH

- Federal Water Pollution Control Act prohibits discharge of oil in U.S. waters.
- Requirement of all U.S. port vessels to have a SPCCP to address spills.

4.3.2 Estuarine Conservation Measures – Coastal Pelagic, Groundfish, and Pacific Salmon EFH

- Perform all slip, access channel, Navigation Reliability Improvementsduring lower abundance of the most susceptible fish life stage of the Pacific Coast Salmon Management Group, October 1 through February 15.
- Implement a water quality monitoring program during dredge operations to assess the need for operational controls that assure turbidity levels remain within seasonal permitted limits.
- Implement operational controls to assure compliance with water quality criteria in the CWA Section 401 Certification, which may include ceasing dredging, decreasing cutterhead speed, increasing suction flow rates and using different size or type of dredge, lowering the crest elevation, and/or avoiding sediment stockpiling during peak ebb conditions.
- For the LNG facility, implement a site-specific SPCCP to minimize the potential for accidental releases of hazardous materials.
- During the initial year(s) of operations, monitor LNG carrier transits in Coos Bay to confirm speeds of four to six knots.
- Conduct LNG carrier ballast water exchanges to include both flushing and treatment prior to entering U.S. waters to reduce the transfer of invasive species to the Coos Bay ecosystem.
- Provide low intensity lights on docks and consult on final design to best assure lighting minimizes conditions that could result in fish attraction or predation.
- To the extent possible, use a vibratory hammer to avoid adverse in-water noise effects. Minimize the use of impact driving except for proofing in-water piles.
- Use sound attenuation measures to minimize adverse in-water noise effects from pile driving with an impact hammer;
- Limit total impact strikes per day to less than 3,000 or another amount determined in consultation with NMFS for in-water piles.
- Conduct much of the slip excavation in the dry out of estuarine waters to reduce effects of turbidity and sedimentation on small forage fish with low swimming ability and on other benthic and epibenthic prey species.
- Implement *Hydrostatic Testing Plan* methods to equipment use and cleaning to reduce invasive species spread or entry to the estuary.
- Mitigate for construction that would involve the loss of intertidal and subtidal habitat by restoring habitat at a 3:1 ratio in Kentuck Slough, and for eelgrass lost by planting eelgrass at a 3:1 (appendix O/Compensatory Wetland Mitigation Plan).

4.3.3 Riverine Conservation Measures – Pacific Salmon EFH

- Extensive erosion control methods would be employed including temporary and permanent slope breakers, sediment barriers, mulch, and erosion control fabric.
- Long-term erosion control including final cleanup, final grading, installation of permanent erosion control structures, backfilling and regrading as necessary, and timely preparation of suitable seedbed.
- OHV barriers to reduce post-construction sediment to streams.
- Revegetation including tree seedlings and replanting conifers where appropriate within 15 feet of the right-of-way center, which would aid future stream shading, organic input, and future LWD supply.
- Stump retention on stream banks to improve intermediate-term stream bank stability.
- Narrowing of right-of-way to 75 feet at stream crossing to reduce loss of riparian vegetation and function.
- Stream bank restoration following trenching including returning banks to preconstruction contours where possible and revegetation (see the ECRP).
- Procedures are in place to keep all petroleum products away from stream entry.
- Provide special additional BMPs at stream crossings that have moderate to high risk of channel or stream bank instability resulting from stream morphology or crossing methods at the specific location.
- Provide post-construction monitoring of all stream crossing sites to ensure streambed and bank conditions remain stable.
- Backfill the surface foot of the excavated stream channel with gravel or native cobble except where stream channels did not have this as native material.
- Follow the *Fish Salvage Plan* details including use of collection methods and procedures that would reduce injury and mortality of fish at pipeline crossings and remove fish from potential adverse noise and blasting effects.
- Return removed LWD to the streams following installation and provide additional LWD to fish streams and banks to help maintain or enhance the habitat (see appendix O).
- Additional mitigation to help maintain the ACS on NFS lands and the RMS on BLM lands would also occur that would have direct and indirect benefits to EFH habitat on these lands. This would include actions in watersheds that contain EFH such as:
  - add LWD to several stream miles
  - restore degraded riparian habitat;
  - improve fish passage at existing passage barriers;
  - improve roads and stabilize culverts;
  - pre-thin to improve riparian habitat;
  - decommission and waterbody crossings and close roads; and
  - stormproof roads (e.g., waterbars, ditch cleaning) reducing risk of road failure that would add fine sediment to streams.

4.4 EFFECTS DETERMINATION

4.4.1 Highly Migratory Species EFH

The proposed action **would not adversely affect** EFH for highly migratory species because accidental spills and releases at sea, if they should occur, are not expected to diminish water quality within the marine analysis area. The volumes of hydraulic oil and fuel spills from a single LNG carrier would be very small in relation to the size of the ocean.

4.4.2 Coastal Pelagic Species EFH

The proposed action **may adversely affect** EFH for coastal pelagic species in the short-term due to loss of eelgrass habitat until such habitat is re-established at the eelgrass mitigation site and until disturbed estuarine habitat is restored and recovers. Short-term loss of benthic food resources would also result from dredging of the access channel and NRI areas. Small juvenile and larval stages of fish could be entrained or impinged and suffer mortality from the cooling water intakes of LNG carriers while at berth; but a substantive loss is unlikely.

4.4.3 Groundfish EFH

The proposed action **may adversely affect** EFH for groundfish species in the short-term due to loss of eelgrass habitat until such habitat is re-established at the eelgrass mitigation site and until disturbed estuarine habitat is restored and recovers. Short-term loss of benthic food resources would also result from dredging of the access channel and NRI areas. Over the long-term, eggs, larval, and small juvenile life stages of fish occupying waters near the LNG carriers at the Terminal dock could be entrained or impinged, and suffer mortality by cooling water intakes, but a substantive loss is unlikely.

4.4.4 Pacific Salmon EFH

Effects to freshwater Pacific Coast Salmon EFH by the proposed action **may adversely affect** riverine habitats by impacting substrates and suspended sediment water quality over the short-term, as well as by removal of riparian vegetation, which could affect LWD supply over the long-term. Also, juvenile coho or Chinook salmon entrapped in isolated areas at pipeline stream crossings, as well as removal from stream crossing areas, would result in minor fish mortalities. Short-term loss of benthic food resources would also occur from slip dredging. Juvenile salmon stages could be entrained or impinged, and suffer mortality from cooling water withdrawal in the estuary.

1.0 THERMAL PLUME STUDY

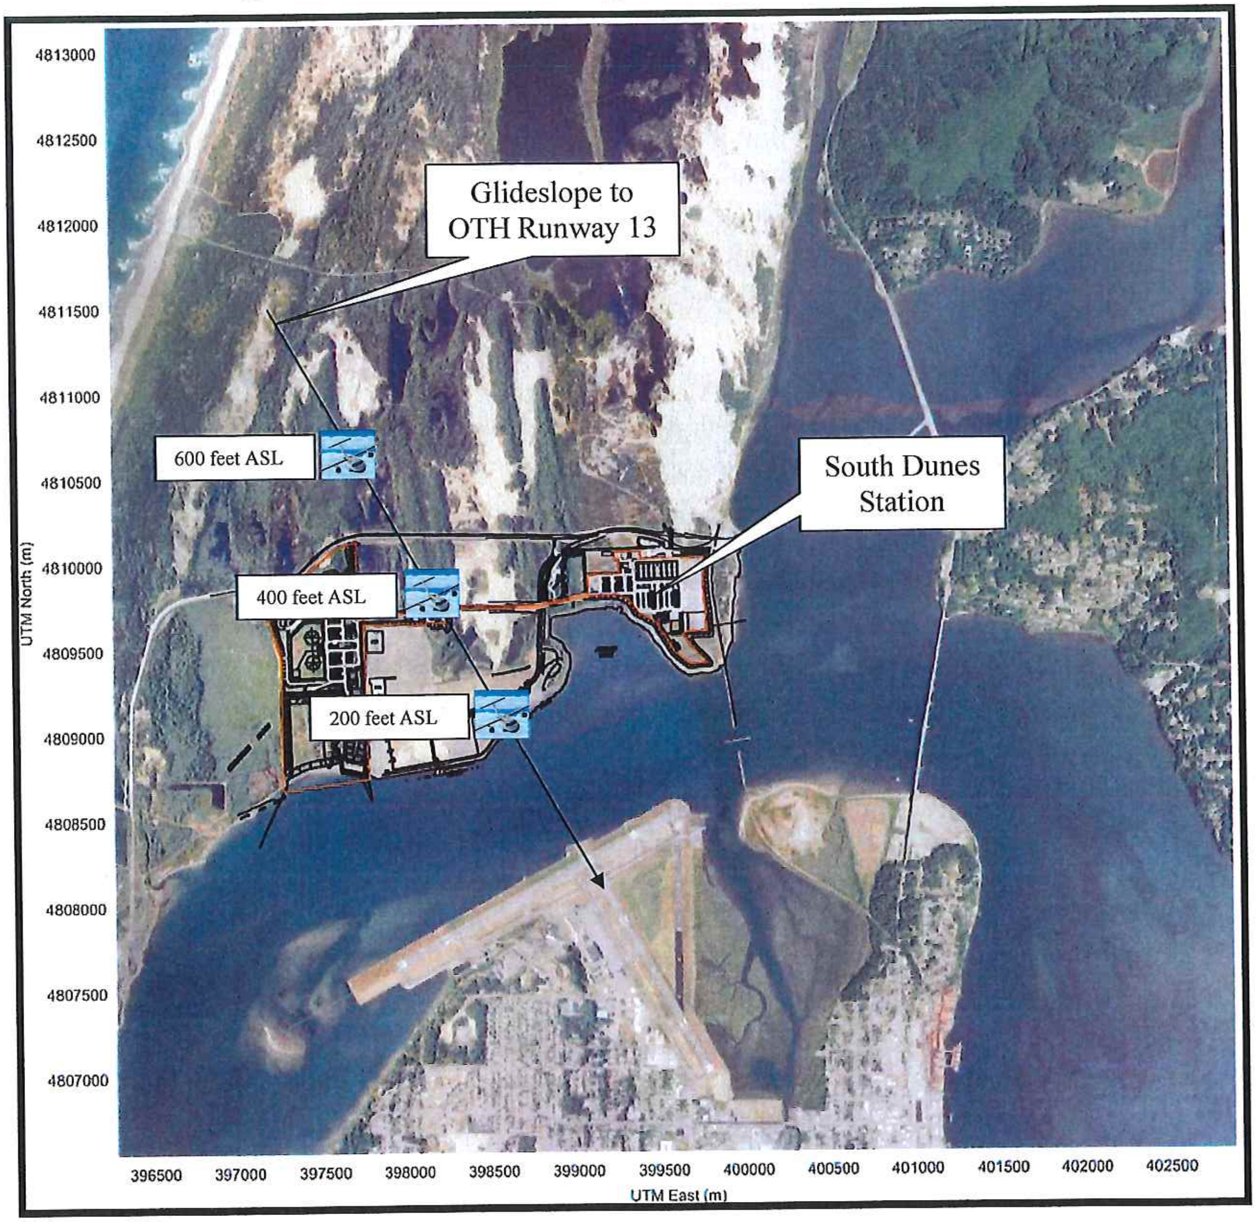
1.1 Introduction

Jordan Cove Energy Project, L.P. is proposing to construct and operate a liquefied natural gas (LNG) export terminal on an approximate 168-acre site located on the bay side of the North Spit of Coos Bay, Oregon between Coos Bay Navigation Channel Miles (CM) 7.0 and 8.0. The project, known as the Jordan Cove Energy Project (JCEP) LNG Terminal Project, or Project (or Facility) will consist of facilities to receive, liquefy, temporarily store, and send out up to approximately six million metric tons per annum (MMTPA) of LNG. The LNG terminal will be capable of loading LNG ships ranging in capacity from 89,000 cubic meters (m^3) to 160,000 m^3. The LNG loaded onto the ships will be transferred by cryogenic service piping from two 160,000 m^3 (1,006,000 barrels) full-containment LNG storage tanks where it will be stored in a liquefied state until it is pumped out to the LNG vessels. The following liquefaction facilities are proposed for the Project:

- Four liquefaction trains, each with the capacity of 1.5 MMTPA;
- Two feed gas cleaning and dehydration trains with a combined natural gas throughput of approximately 1 billion SCF/day (Bscf/d);
- Refrigerant storage and resupply system;
- Aerial Cooling System (Fin-Fan) to reject heat removed during the LNG liquefaction process; and
- The South Dunes Power Plant, a nominal 420 megawatt (MW) natural gas fired combined-cycle electric power plant for the purpose of powering the natural gas liquefaction process systems.

The proposed Project will utilize five GE LM6000 PG combustion turbines, each with an exhaust stack 119 feet above grade (or 167 feet above sea level (ASL)), used primarily for powering the natural gas liquefaction process systems. The proposed Facility will be located at approximately 43.434024 North Latitude, 124.243219 West Longitude, North American Datum 1983 (NAD83). The approximate Universal Transverse Mercator (UTM) coordinates of the proposed facility are 399,383 meters Easting, 4,809,765 meters Northing, in Zone 10, NAD83. The project site is proximate to the normal air traffic patterns of North Bend Municipal Airport (currently known as the Southwest Oregon Regional Airport or OTH), which is approximately located 1.6 km to the South of the proposed South Dunes Power Station. Figure 1-1 shows the location of the South Dunes Station along with the glide slope to runway 13 of the Southwest Oregon Regional Airport.

Figure 1-1: Site Location Map with glideslope to OTH



An analysis of the potential for the South Dunes Power Station and Gas Conditioning system exhaust plumes to impact flight operations directly over the proposed Project was made in accordance with a request from Jordan Cove Energy Project, L.P.

1.2 Vertical plume velocity guidelines

The Federal Aviation Administration (FAA) has identified thermal plumes as being a potential flight hazard where pilots should avoid flight in the vicinity of those plumes (Section 7-5-15 of the Aeronautical Information Manual: Official Guide to Basic Flight Information and ATC Procedures, February 2012). The FAA has issued guidance for pilots to fly upwind of possible thermal plumes in order to avoid the potential for the high temperature thermal exhausts to cause air turbulence around the aircraft. The FAA currently does not have any guidelines for conducting thermal plume assessments but is currently conducting studies to further characterize the effects of thermal plumes. Until those FAA studies are completed, pilots are encouraged to exercise caution when flying in the vicinity of thermal plumes.

Since the development of a simple-cycle gas turbine power station at the end of a runway in Australia in the mid-1990s, the Australian Civil Aviation Safety Authority (CASA) has taken an active role in the review of the siting of facilities with the potential to affect aviation activities. Potential hazards that could affect the safety of aircraft include tall visible or invisible obstructions. Invisible obstructions include industrial exhausts that generate significant turbulence due to high velocity and buoyancy. CASA has issued an Advisory Circular, (CASA-AC-139-5, 2012) that specifies the requirements and methodologies to be used to assess whether a new industrial plume is likely to have adverse implications for aviation safety. The CASA guidance includes a range of critical plume velocity (i.e., the velocity at which the vertical plume rise may affect the handling characteristics of aircraft in flight such that there may be a momentary loss of control) of between 4.3 and 10.6 meters per second (m/s). The selection of critical plume velocity is based upon a range of considerations including the phase of flight affected, the size of aircraft, the frequency of use of flight path, presence of air traffic control, and human factors. It should be noted that a vertical velocity of 4.3 m/s is associated with typical towering cumulous clouds while cumulonimbus clouds (i.e., thunderstorms) typically have vertical velocities in the 10-25 m/s range.

The aim of this assessment is to determine the potential for the plumes emitted from the Project to exceed the minimum critical plume velocity of 4.3 meters per second (m/s) within the flight path to the Southwest Oregon Regional Airport.

1.3 Stack Exhaust Characteristics

The assessment focused on the Project components most likely to generate a plume vertical velocity that could exceed the critical plume velocity. Therefore, the assessment focused on those Project components with the most substantial momentum flux at stack exit and buoyancy flux at stack exit, which is a function of exhaust flow and temperature. The facility equipment, that would generate the greatest plume vertical velocity are the five GE LM6000 combustion turbines due to their large volumetric flows and proximity to one another. Thus, this study focused on determining a maximum calculated vertical velocity due to the combustion turbine exhaust plumes.

The Project also utilizes thermal oxidizers as part of the gas conditioning systems and air cooled condensers as part of the combined cycle power plant operations. The total combined volumetric flow rate from the two thermal oxidizers is 4% of the total flow from the five combustion turbines. Thus, it is expected that the plume vertical velocity generated from the thermal oxidizers will be substantially lower in magnitude than the plume vertical velocity from the combustion turbine stacks. Similarly, the two air cooled condensers are expected to have a minimal contribution to a plume vertical velocity outside of an immediate area above the units. This is due to the low exit velocity for each fan (typically below 3-5 m/s) and due to the minimal temperature differences between the fan exhausts and the ambient temperature. For these reasons, it is expected that the buoyancy flux and momentum fluxes would be minimal outside of the direct area above the units (i.e., within a few hundred feet above the fan deck).

The stack exhaust characteristics for each of the five combustion turbines are shown in the following Table 1:

Table 1: Combustion Turbine Exhaust Characteristics

Stack Exhaust Parameters	GE LM6000 Combustion Turbines	
	English	Metric
Height	119 feet	36.27 meters
Flowrate	355,123 ACFM	167.6 m^3/s
Velocity	75.36 ft/sec	22.97 m/s
Temperature	251.8 F	395.3 Kelvin
Diameter	10.0 feet	3.05 meters

1.4 Modeling Methodology

This assessment was based upon both a conservative theoretical approach, which determines the potential for turbulence generated by the plume-averaged vertical velocity of Project's exhaust plumes as well as a conservative modeling approach using the Project design and local meteorological conditions. Additional approaches using typical meteorological conditions were also developed to provide representative plume vertical velocities.

Theoretical Approach

This method uses worst-case assumptions of calm winds and neutral atmospheric conditions for the entire vertical extent of the plume to determine the worst-case impacts. It should be noted that this methodology determines the maximum potential vertical velocity in the direct airspace above the South Dunes Station combustion turbine exhaust stacks but does not determine the vertical velocities as a function of horizontal distance from the stacks. This theoretical approach is presented to define the critical plume height at which, the vertical velocity exceeds the threshold of 4.3 m/s.

The methodology followed in this assessment is outlined in the Aviation Safety and Buoyant Plumes paper presented at the Clean Air Conference in South Wales, Australia, by Peter Best et al. This paper is included in Appendix A. The methodology presented and used in the assessment has been based upon well-verified laboratory and theoretical treatments of the rise and spread of a buoyant plume. The plume growth involves several stages of development detailed below:

Stage 1: In the first stage near to the stack exit, the high plume momentum results in a short distance in which the conditions at the center of each plume are unaffected by ambient conditions. The potential plume core in which maximum vertical velocity and temperature remain constant extends to a distance of approximately 6.25 * D (where D is stack exit diameter) in calm wind conditions. At the end of this stage, the plume average vertical velocity is approximately half of the stack exit velocity.

Stage 2: The plume dynamics and trajectories in this stage respond to ambient air, with much cooler air being entrained into the outer regions of the plume. The momentum and buoyancy of the plume significantly influence the plume rise as this air mixes into the plume and provides dilution to decrease plume vertical velocities. This dilution is sensitive to ambient wind speeds and thus, the use of calm wind conditions is considered to be conservative.

Stage3: At this time the plume rise is due entirely to the buoyancy of the plume and continues until such time that there is an equalization of turbulence conditions within and outside of the plume. This final rise occurs at considerable distances and heights from the stack exit and where the effective vertical velocity would be close to zero. This stage is not assessed quantitatively as near-zero vertical velocities are associated with minor to negligible turbulence.

In addition to the theoretical approach for calculating potential plume vertical velocities based upon calm wind conditions, an alternative methodology was utilized for calculating expected vertical velocities based upon more typical meteorological conditions at the site. This approach utilized more typical horizontal wind conditions expected at the site (based upon the 20th percentile recorded wind speed at OTH of 2 m/s) rather than the worst-case assumption of calm winds throughout the plume. The methodology followed for the typical meteorological conditions assessment is outlined in the paper: Potential for Power Plant Stack Exhaust to Disrupt Aircraft Operations (Joel Reisman and David LeCureux). The methodology presented and used in the assessment has been based upon well-verified laboratory and theoretical treatments of plume rise that is utilized by U.S. EPA in most of their dispersion models.

Modeling Approach

Using the combustion turbine exhaust parameters presented in Table 1, modeling was performed using the AERMOD computer dispersion model to assess the minimum plume dilutions within vertical planes in the regional area around the South Dunes Station. The modeled plume dilutions were then used to develop volumetric averaged plume temperatures resulting in theoretical maximum vertical velocities in both the horizontal and vertical planes around the South Dunes Station. In addition to the using the minimum modeled plume dilutions (i.e., the maximum modeled concentrations) an additional case was developed utilizing more typical, albeit infrequent, meteorological conditions based upon the 98th percentile maximum modeled concentrations. By using this methodology, a vertical velocity was calculated based upon meteorological conditions that would be expected to occur only 175 hours in a year.

The AERMOD model is a state-of-the-art steady-state Gaussian plume model that can be used to assess concentrations from a wide variety of sources associated with an industrial source complex. The model includes the PRIME (Plume RIse Model Enhancements) algorithm for improved treatment of building downwash and cavity area effects. Specifically, the AERMOD model with PRIME features enhanced plume dispersion coefficients due to the wake turbulence and reduced plume rise caused by descending streamlines and increased entrainment in the wake of a structure. One of the important aspects of the PRIME algorithm is its ability to model the downwind turbulent cavity (i.e., near wake) and far wake areas on a three dimensional scale. Thus, the AERMOD model is preferred for modeling the South Dunes Station combustion turbines given the large number of building tiers and structures on the site that create a variety of turbulent cavity regions. The AERMOD model is applicable for assessing the air quality concentrations for locations at industrial sources where aerodynamic downwash is important, in rural or urban areas, in flat or rolling terrain, and for point elevation above ground level.

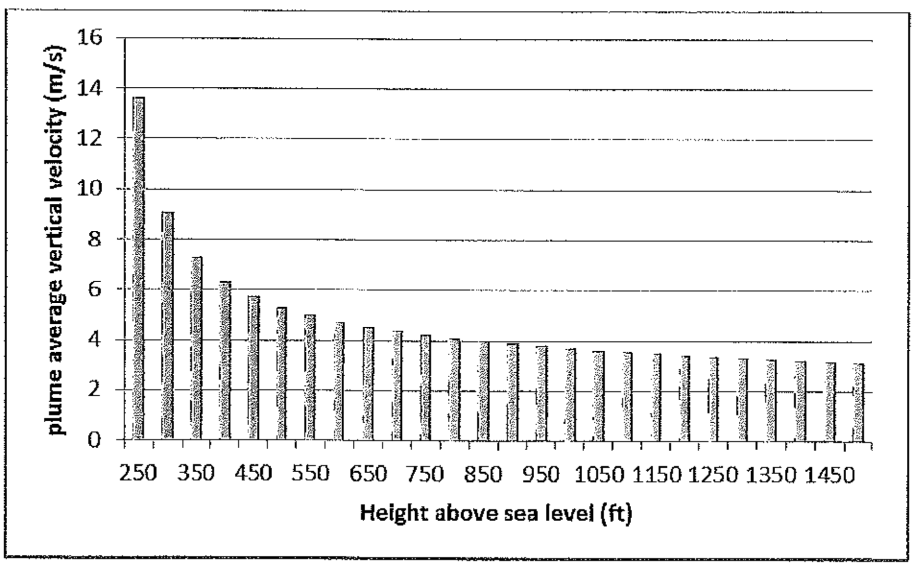
The thermal plume analysis utilized five years of meteorological data collected from 2007-2011 from the meteorological tower at the Southwest Oregon Regional Airport. The assessment focused on a 10 km x 5 km area starting at the landing point of Runway 13 at the airport. Vertical planes were developed for 100 feet vertical increments at levels from 100 feet to 1,000 feet ASL (i.e., the heights at which the maximum vertical velocities may be expected to occur from this Project).

The modeled plume dilutions across the 5 years of meteorological data and over the 50 square kilometer horizontal planes at ten heights were then utilized to develop volumetrically averaged plume temperatures. The difference in plume temperature and ambient temperature would lead to the acceleration of an air parcel due to the density differences at a given level. A conservative method to calculate plume vertical velocity was developed using the meteorological concept of convective available potential energy (i.e., CAPE or potential buoyancy) that is typically used to calculate the maximum theoretical vertical velocity of thunderstorms.

Using the modeled plume temperatures, a convectively driven vertical velocity is calculated at each modeled level by integrating (i.e., summing) the calculated layer CAPE at each 100 ft vertical increment above sea level. This methodology assumes that positive buoyancy will occur at each modeled level such that the vertical velocity will keep increasing until it reaches the equilibrium level (i.e., the level at which the plume temperature equals the ambient temperature). This methodology results in a conservative estimate of vertical velocity in a column of air since it is based upon layering maximum modeled plume temperatures regardless of the time and space that they would occur.

1.5 Modeling Results

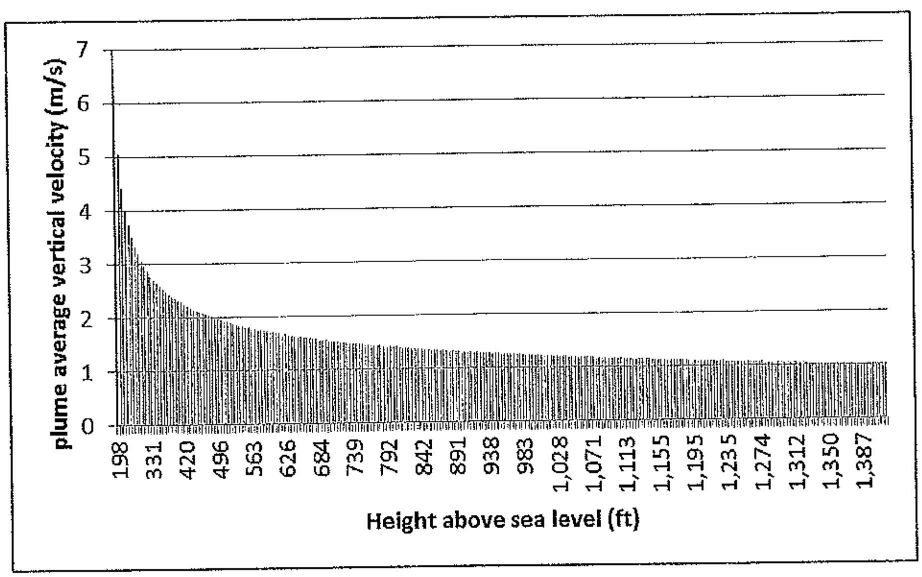
Using the methodologies described in Section 1.4, the maximum theoretical plume vertical velocity was calculated for the area directly above the South Dunes Station exhaust stacks. The results are detailed in Appendix B and summarized in the following chart at various heights above sea level.



As shown in the chart, the vertical velocity exceeds the threshold of 4.3 m/s up to a height of 750 feet above sea level. The values presented in the chart above are very conservative estimates of the plume average vertical velocity as they assume the wind profile is constant with height and with no wind shear but in reality, there is considerable variation with height in light winds and even light horizontal winds would substantially reduce the predicted vertical velocities. Also, these vertical velocities are for the area directly above the South Dunes Station exhaust stacks. For example, even at a height of 1,500 above sea level the plume radius would be on the order of 200 feet from the stack centerline.

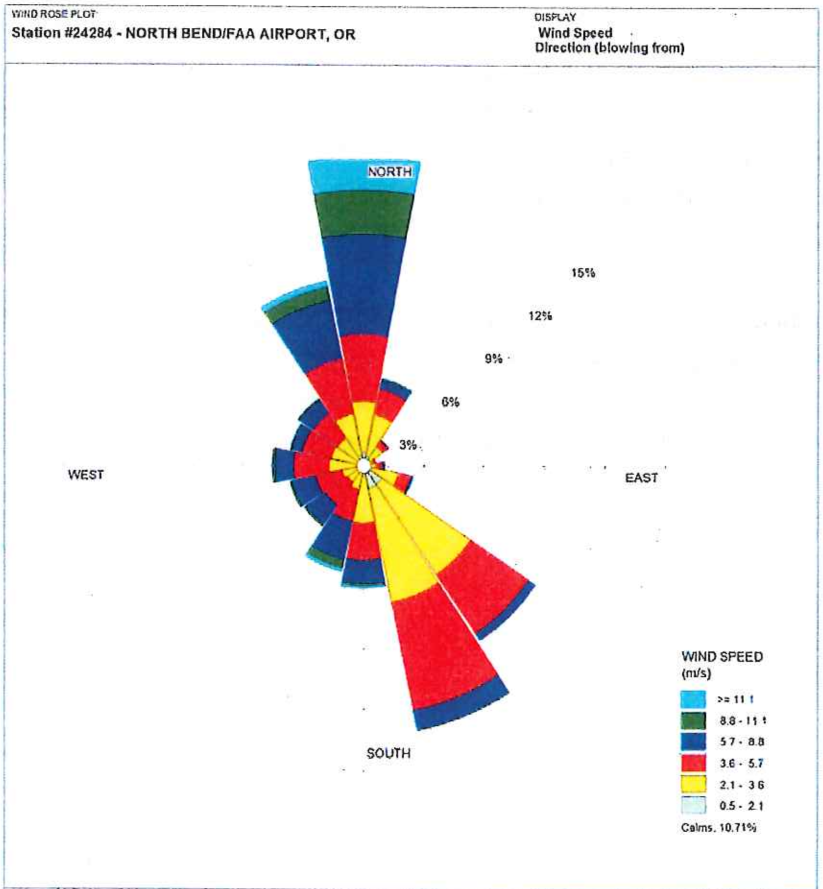
As shown in Figure 1-2 the frequency of calm winds in Coos Bay is approximately 10% of the year on an annual basis. The majority of winds occur from the North/Northwest and from the South/Southeast such that the plumes from the South Dunes Station would infrequently travel within the glide path to OTH. Additionally, winds from the East that would serve to push a plume into the glideslope to OTH Runway 13 occur infrequently (5% of the year) and at speeds greater than 2 m/s.

The results of the theoretical modeling assuming a minimal horizontal wind shear (i.e., a wind speed of 2.0 m/s) indicates that the vertical velocity exceeds the CASA threshold up to a height of 70 feet above stack top or 234 feet above sea level. A wind speed of 2.0 m/s or less would be expected to occur up to 20% of the year at the site. These results are summarized in the following chart.



The results of the modeling using five years of meteorological data with the AERMOD dispersion model are presented graphically at three flight levels (i.e., 200 feet, 400 feet, and 600 feet) in Appendix C with the units of meters per second. As shown in the graphics and as expected, there is a substantial vertical velocity gradient over the South Dunes Station, which confirms the results of the theoretical modeling presented earlier in regards to magnitude and horizontal extent of the plume. By using the 98th percentile modeled concentration results (representing the dispersion resulting in worst case plume vertical velocities for 175 hours per year) the results show that the CASA threshold is exceeded in the general direct airspace above the South Dunes Power Plant and quickly dissipates to less than 1.0 m/s in the direct flight path to the airport.

Figure 1-2: Southwest Oregon Regional Airport Windrose



1.6 Summary of Results

An assessment of the plume-average vertical velocity associated with the operation of the South Dunes Station combustion turbines was conducted using both conservative theoretical and modeled methodologies and for both worst-case and typical meteorological assumptions. The results of the theoretical assessment indicate that there is a potential for the CASA vertical velocity threshold to be exceeded up to a height of approximately 750 feet above sea level over the South Dunes Station exhaust stacks (at this height the plume diameter is approximately 180 feet under calm wind conditions). However, even by assuming a more realistic amount of horizontal wind shear, the calculated extent of exceedances of the CASA threshold extends to approximately 230 feet above sea level.

The results of the modeled assessment also indicate that the CASA vertical velocity threshold may be exceeded within the airspace above the South Dunes Station. It is expected based upon both the theoretical and modeled assessments that the CASA threshold would not be exceeded in the flight path to the airport under more typical, albeit still infrequent, wind conditions from those used in the worst-case assessment. Under these more typical meteorological conditions the CASA threshold would not be expected to be exceeded other than in the area directly above the South Dunes Power Plants exhausts.

The results of the assessment confirm the FAA guidance for pilots to fly upwind of possible thermal plumes in order to avoid the potential for the high temperature thermal exhausts to cause air turbulence around the aircraft. Specifically, in the airspace directly above the South Dunes Station there exists the possibility of exceeding the CASA thresholds such that pilots should avoid flight in the vicinity of those plumes.

Summary

Very buoyant plumes generally experience good dispersion but can, in some circumstances, affect aviation safety. Large in-plume vertical velocities can occur in calm conditions with minimal wind shear. Recent civil aviation guidelines seek to restrict the horizontal or vertical extent where average in-plume vertical velocities exceed a threshold that can threaten aircraft performance or structural stability. Key plume calculation procedures require adequate predictions or measurements of vertical profiles of wind and turbulence parameters. The TAPM scheme proves useful but requires additional features for complex source geometry. A hybrid approach overcomes most of these limitations, whilst treating the initial plume development in more detail. Design issues for typical stack configurations are discussed.

Keywords: Plume velocities, stacks, cooling towers, flares, safety

1. Introduction

Over the past 25 years, considerable laboratory, field and theoretical work has been undertaken on the dispersion of very buoyant plumes from industrial sources. Such sources have traditionally included single or multi-flue stacks for major power stations, cooling towers and gas turbine generating plants where large volume flows, together with high exit temperatures, produce some of the highest buoyancy fluxes for normal power station configurations. With the increasing emphasis on gas and similar alternatives for power generation and the recent consideration of stack-in-tower configurations for locations where dry cooling is preferred, highly buoyant plumes are becoming the rule. In addition, industrial flares or unintended releases from pressurised pipelines can yield plumes with large momentum and/or buoyancy fluxes and may have structures approximating line or area sources. Recent dispersion analyses (Weil et al 2001) have shown that very buoyant plumes can readily interact with the overlying inversion and have plume spread dominated by buoyancy for most of the near-field. Plume rise and spread descriptions may need to be revisited.

High buoyancy plumes can, however, give rise to other problems that may require addressing in environmental impact assessments. High buoyancy plumes rise quickly and have significant in-plume vertical velocities. Should the facility be close to local airfields or aviation transport routes, any aircraft encountering the buoyant plumes may experience sufficient vertical uplift and turbulence to cause some temporary disruption to the manoeuvrability of aircraft, especially light commercial (rather than jet) aircraft.

There are no publicly-available field studies that document the decline of in-plume velocities with plume travel time for a variety of conditions necessary to produce validated modelling schemes. Various experimental and theoretical work was conducted around open-cycle and combined-cycle gas turbines at Kuala Lumpur, with field measurements taken for stack-top windspeeds in the range 2-8 m/s (but not for calm conditions). The Cessna aircraft used (Flinders Institute for Atmospheric and Marine Sciences) was fitted out to measure turbulence and air quality parameters as well as aircraft variables. The unpublished results showed a strong decrease of in-plume vertical velocities with windspeed and height, core vertical velocities a factor of approximately 2 greater than plume-averaged values and significant influences on aircraft handling for near-instantaneous (~ 1 sec) exposures to strong plume velocities, especially if encountered by surprise.

The importance of vertical motion in causing aviation problems is better documented by the number of light aircraft incidents reported during strong convection in Australia (Spillane and Hess 1988). During extreme events, naturally-occurring vertical velocities can reach 8 m/s.

The current studies were conducted for an environmental impact assessment of a 700 MW open cycle gas-fired turbine near an army aviation centre at Oakey in southern Queensland. Previous studies by Spillane (1980) on moist plumes were adapted to treat buoyant plumes from closely located sources in calm and low windspeed neutral conditions (Katestone

Scientific 1997). At the time, there was no model recommended by the Civil Aviation Safety Authority of Australia (CASA) and, indeed, very little guidance internationally as to the manner in which available velocity thresholds should be interpreted. Representations were made and generally accepted that the threshold vertical velocity of 4.3 m/s recommended by Australia and New Zealand authorities should be viewed as a plume-average rather than plume centreline criterion.

Critical (but extreme) aviation conditions are expected to be very light winds and neutral stability to heights of 500 m or more. For most assessment sites, there is unlikely to be a substantial database of near-surface and upper-level wind and temperature information to estimate the frequency of occurrence of such rare cases. Recognising this, CASA recently recommended the use of the CSIRO TAPM model for producing long-term databases of such profiles at any location within Australia and for providing a publicly-available method of calculating plume vertical velocities in the near-field of a single plume source (CASA 2003). The TAPM treatment of plume rise (Hurley and Manins 1995) uses coupled non-linear first-order differential equations for the plume volume G, buoyancy F and momentum M fluxes that are generalisations of the original Briggs (1975) plume rise formulation, based on the work of Glendening et al (1984) for stable atmospheres with complex structures. The TAPM scheme does not include any influence of source-altered flow fields or moisture content. It is also strictly valid only for single sources, with multiple sources being treated only via use of a plume enhancement factor, a relatively coarse device for describing near-field plume dynamics. For cooling tower sources, moisture emissions, the confluence of adjacent plumes and the influence of suction occurring due to tower bypass flow can be important (Rezacova and Sokol, 2000). This paper restricts attention to essentially dry plumes with no interactions with distorted flow fields.

Aviation safety risk assessments require the evaluation of concurrence of adverse vertical velocities with the presence of aircraft in the vicinity of the plume and a spectrum of aircraft types and pilot skill. Ideally, a generalised scheme should facilitate the prediction of likely pilot response to such events but publicly-available schemes are not yet available. As for many air quality problems, the main difficulties are assessing the relevance of traditional techniques to the forecasting of extreme conditions and determining the reliability of such assessments based on existing knowledge.

The present paper outlines the available plume calculation methodologies for the Spillane and TAPM approaches, addresses the modifications necessary for multiple sources and assesses the utility of the various schemes for dispersion and meteorological modelling in providing initial and detailed assessments. The high buoyancy of the plumes diminishes the utility of various design alternatives such as increasing stack separation, reducing exit velocity and changing the orientation of discharge. Practical measures are discussed.

2. General considerations

For the generic stack problem, we choose the case of multiple but identical sources of high initial exit velocity and temperature but low enough water vapour content to neglect latent heat considerations. In light winds, influences of the aerodynamic wakes or other effects of stack or cooling tower structures can be neglected. The initial stage (exit conditions) is assumed to be a plume emanating from a stack of height h_s and diameter D, with plume exit velocity either uniform over the cross-section (with a value V_{exit}) or, more likely, a non-uniform velocity profile with plume average velocity V_{exit}. The exit virtual potential temperature θ_s, volume flow $\pi D^2 V_{exit}/4$ and initial buoyancy flux $F_o = gV_{exit} D^2 (1 - \theta_a/\theta_s) / 4$ are readily calculated, with θ_a denoting ambient conditions. The ambient airspeed at stack top is denoted u_e with $K_o = V_{exit}/u_e$ being the initial plume to ambient velocity ratio.

An outline is given in the following sections of the Spillane and TAPM plume dynamics modules for single plumes (retaining their respective notations). The physical interpretation of the processes is outlined in Section 3 with the additional considerations needed for multiple plumes.

2.1 Spillane methodology

The plume radius a, orientation ϕ and velocity V are followed along the plume trajectory. Five equations are solved numerically for the normalised vertical velocity $K = V/u_e$:

Radial growth of a forced-plume bending in a wind:

$$\frac{da}{ds} = \beta_n \cos\phi / K + \beta_e \left| 1 - \frac{\sin\phi}{K} \right| \quad (1)$$

Rate of entrainment, E, into the plume:

$$2E / V = (\frac{da}{ds} + (\lambda^2 \cos\phi) / 2F_r^2) / (1 - \sin\phi / 2K) \quad (2)$$

Momentum flux, Va, (longitudinal)

$$\frac{d(Va)}{ds} = 2E - V\frac{da}{ds} \quad (3)$$

Trajectory curvature; transverse momentum flux

$$\frac{d\phi}{ds} = \left(2\,Ea\,u_e \cos\phi - \left(F \sin\phi\right) / 2.25V\right) / \left(Va\right)^2 \quad (4)$$

Flux of heat:

$$\frac{d\left(Va^2 \Delta\theta / \theta\right)}{ds} = 0, \text{ in a neutral environment} \quad (5)$$

where the notation is as follows:

8557

Exhibit 37

a = plume top-hat radius;
s = distance along plume trajectory;
ϕ = angle of plume centre line to vertical ;
$K = V/u_e$;
V = plume-averaged speed.
$\beta_n = 0.40$; $\beta_e = 0.16$; $\lambda = 1.11$;
F_r^2 = Froude No = $V^2/(ag\Delta\theta/\theta)$
F = flux of buoyancy = $\lambda^2a^2Vg\ \Delta\theta/\theta$; $\Delta\theta = \theta_p - \theta_e$ and suffices p and e for plume and environment.
θ = virtual potential temperature.

Initial conditions for ϕ, V, a and z are set for the end of the momentum rise stage (for a single plume) or at the end of the merged plume stage (for multiple plumes). An along-plume distance step of Δs = 20 m is used, and the appropriate value of $u_e(z)$ adopted for non-uniform profiles.

For the case of calm conditions, analytic solutions are possible, one for the product Va at any height, the other a linear increase of $a = 0.16\ (z - z_v)$ where the virtual source height (above stacktop) $z_v = 6.25\ D\ [1 - (\theta_e / \theta_s)^{1/2}]$. For $z > 6.25\ D > z_v$ we have:

$$(Va)^3 = (Va)_o^3 + 0.12 F_o \left[(z - z_v)^2 - (6.25D - z_v)^2\right]$$
$$\text{where } (Va)_o = V_{exit}\, D/2\,(\theta_e/\theta_s)^{1/2} \qquad (6)$$

2.2 CSIRO TAPM methodology

The TAPM mean plume rise estimation takes the Glendening et al (1984) approach but assumes that the horizontal plume velocity instantaneously takes up the ambient horizontal velocity at stack height. Cartesian co-ordinates are adopted. The differential equation for plume volume flux G:

$$\frac{dG}{dt} = 2R\ w_p\left(\alpha\ w_p + \beta\ u_e\right) \qquad (7)$$

neglects a third term due to ambient turbulence entrainment. $w_p = \frac{dz_p}{dt}$ is the plume vertical velocity, α = 0.1 and β = 0.6 are vertical and bent-over entrainment coefficients and R is the plume radius. For the buoyancy flux F, it assumes:

$$\frac{dF}{dt} = -\frac{sM}{u_p}\left(A u_a + w_p\right) \qquad (8)$$

where $s^2 = \frac{g}{\theta_a}\frac{\partial\theta_a}{\partial z}$ gives the ambient buoyancy frequency (s = 0 in neutral conditions), $u_p^2 = u_e^2 + w_p^2$, A = 1/2.25 and M is determined by $\frac{dM}{dt}$ = F (= F_o in neutral conditions). By definition,

$$G = \frac{\theta_e}{\theta_p} u_p R^2,\ F = g u_p R^2 \frac{\Delta\theta}{\theta_p},\ u_p R^2 = G + F/g,$$
$$w_p = M/G \qquad (9)$$

Initial conditions are set with G, F and M evaluated with $w_p = V_{exit}$, $R = R_s = D/2$ but with the initial integration having

$$R = R_o = R_s\left(V_{exit} / \left(u_a^2 + V_{exit}^2\right)^{1/2}\right)^{1/2} \qquad (10)$$

The plume rise height is terminated when F = 0 and plume and ambient dissipation rates are equal. The plume dimensions are based on $R = 0.4\ (z - h_s)$ or equivalent prescriptions.

3. Treatment of multiple plumes

For N multiple, identical sources with stack separation d, Table 1 summarises the expected multi-stage plume development as well as Figure 1. The first stage is the rapid (almost vertical) rise of the individual plumes due to their momentum. The external surface of the plume entrains air as it rises (and the vertical velocities are reduced). The end of the momentum-dominated phase occurs when this entrainment reaches the plume core, the plume centreline has a vertical velocity equal to V_{exit} and the velocity profile will be essentially Gaussian. The peak (core) vertical velocity is therefore V_{exit} but the plume average value is 0.5 V_{exit}. Conservation of momentum therefore requires the plume width to have effectively doubled from its initial value a_o.

In this first phase, the plume travels a height of 6.25 D in calm conditions and 0.4 K_oa_o for K_o reasonably large (based on laboratory experiments). Davidson (1994) has also shown that an analytic form for plume rise in a uniform wind has an initial component of 6.2 D exp (-3.3/K_o).

In the second stage, the plume dynamics and trajectories respond to ambient conditions, with much cooler air being entrained into the stack plume. The buoyancy of the plumes has significant influences on the rise as this air mixes into the plume and provides dilution of the exhaust. This dilution is very sensitive to ambient wind speed. For multiple plumes from closely-spaced stacks, this leads almost immediately to a height at which two plumes first touch each other (and plume merging commences) when the effective plume radius is equal to half the stack separation (this is exact in calm winds and approximately correct for light winds). Total merging is assumed to occur when the single plume radius equals stack separation. Conservation of buoyancy flux and Froude number (a reasonable assumption for coherent plumes) leads to a conclusion that the plume radius and vertical velocity will be increased overall by a factor of $2^{0.25}$ = 1.189 by the merging of 2 adjacent plumes.

For more than two stacks, the situation is more complex. In calm conditions, the combined plumes from pairs of stacks will coalesce shortly after to form a coherent plume, assumed to be complete before the single plume radius, a^{sp}, is ½ d (N-1) At this height, the combined plume velocity V_m and radius a_m are $N^{0.25}$

greater than for a single plume. For non-calm conditions, a simplified treatment shows that total merging is likely to occur soon after the merging of two adjacent plumes, for winds at right angles to the line of separation of the stack. For winds at smaller angles ω to the line of stacks, the process is more sequential and the effective stack separation can be reduced by a factor proportional to cos ω.

In the third stage of plume development, plume rise is due entirely to the buoyancy of the (merged) plume and continues until there is an equalisation of turbulent conditions within and outside the plume. The effective average vertical velocity is then close to zero. The third stage of plume development can then be treated as that of a single merged plume (with different initial conditions for a, V and ϕ) passing through different atmospheric layers with varying horizontal velocity u_e. The Katestone software uses a simple successive substitution method to determine a, E (the entrainment), V and ϕ in that order. These equations are valid up to a critical value of ϕ_c ($\phi_c < \pi/2$) at which either the assumptions become invalid or plume rise should be effectively terminated.

These equations can be used in the second stage prior to plume touching and in the third stage once merging has been completed. Plume height is calculated by aggregating $\Delta s \cos \phi$, centreline displacement by aggregating $\Delta s \sin \phi$. For each Δs, the appropriate ambient windspeed is determined by linear interpolation (or power law curve fitting of available meteorological profile measurements or predictions).

A fourth stage can occur if the coherent plume reaches the base of the overlying inversion (height Z_i). Some of the plume will punch through the inversion base, albeit with reduced vertical velocity. The remainder will be effectively trapped within the inversion layer with essentially zero vertical velocity. Weil et al (2001) show that the penetration in convective conditions depends on $F_*^{2/3}$ where $F_*=F/(u_e w_*^2 Z_i)$ and w_* is the convective velocity scale. There is as yet little guidance on plume dimensions and vertical velocity for the penetrative component.

Table 1: Key parameters for the various stages of development for merging plumes.

Stage	Average plume velocity		Plume width	Plume height	Plume angle	Comments
	Vertical	Horizontal				
Stack exit	V_{exit}	0	a_o	h_s	0°	
End of jet phase	$0.5 V_{exit}$	$u_e(z) + V \sin \phi_o$	$2a_o$	$h_s + z_o$	ϕ_o	$z_o = K_o a_o < 6.25D$
Plumes first touch	$V_t \cos \phi_t$	$u_e(z) + V_t \sin \phi_t$	a_t	z_t	ϕ_t	$V_t < 0.5 V_{exit}$
End of plume merging	$V_m \cos \phi_m$	$u_e(z) + V_m \sin \phi_m$	a_m	z_m	ϕ_m	$a_m \approx N^{1/4} a^{sp}$ $V_m \approx N^{1/4} V^{sp}$
Coherent merged plume	$V \cos \phi$	$u_e(z) + V \sin \phi$	a	z	ϕ	$V < V_m$ $a > a_m$
Maximum plume rise	0	$u_e(z) + V \sin \phi$	a_c	z_c	ϕ_c	$\phi_c < 90°$
Inversion interaction	Low	Shear-affected	Enhanced	$> Z_i$	Variable	(Weil et al 2001)

4. Illustrative examples

The simplest cases assume identical sources with stack separation d operating in a neutral and unbounded atmosphere with uniform conditions. For the Spillane approach, Table 2 gives the resulting plume-average vertical velocities for the cases with V_{exit} = 38.9 m/s, h_s = 35 m, F = 2300 m^4/s^3 and N = 1 and separately N = 2 with d = 25 m.

The heights experiencing threshold exceedances are dramatically reduced going from calm to light winds. The TAPM approach for single plumes gives similar results if some allowance is made for an initial displacement offset z_0 (Figure 2).

Table 2: Plume average vertical velocities (m/s) for uniform calm and light wind conditions in a neutral atmosphere

Height	Calm		u_e = 1.5 m/s		u_e = 3 m/s	
	Single	Double	Single	Double	Single	Double
100	12.2	12.2	9.0	9.3	6.9	8.3
200	7.8	9.2	5.5	7.0	3.6	5.1
300	6.5	8.0	4.4	5.8	2.6	3.9
500	5.3	6.6	3.2	4.5		2.8
700	4.8	6.0	2.6	3.7		2.2
1000	4.1	5.2

5. Meteorological modelling

Meteorological inputs are critical for a reasonable treatment of risk, especially for near-calm conditions at stack-top and above. Unfortunately, it is these very conditions under which near-surface measurements (together with stability-dependent profile laws) or TAPM-like prediction methodologies are likely to be poor indicators of actual conditions, at least for inland sites (Jackson et al 2003). Presumably this quandary lead CASA to recommend the TAPM approach. If measurements are available from a nearby 30-100 m tower, we would recommend their use unless TAPM results are carefully tuned to the appropriate surface conditions.

Recent project work near Williamtown Airport gave a comparison of five years of hourly TAPM results with available balloon and 30 m tower measurements. The main conclusions were:

- Moderate interannual variability in the actual and predicted occurrence of light winds at 30 m and above.
- TAPM tends to underpredict the frequency of occurrence of very light winds (< 1 m/s) compared to tower observations (typically 1.2 - 3.5% compared to 5.7 - 14.9%).
- For available balloon profiles, TAPM overpredicted the frequency of very light winds at 600 m and 900 m agl.
- Very few measurements are available in the crucial 100-500 m height range.

6. Synthetic approaches

The Spillane approach has been adapted to take in the TAPM wind profile conditions. Figure 3 compares the cumulative probability distributions for critical heights (where the in-plume average velocity drops below 4.3 m/s) obtained by using either the TAPM wind predictions or the interpolated measured winds, for the case of two 35 m high, 54 m separated combined-cycle units of total capacity over 800 MW. Close agreement is obtained.

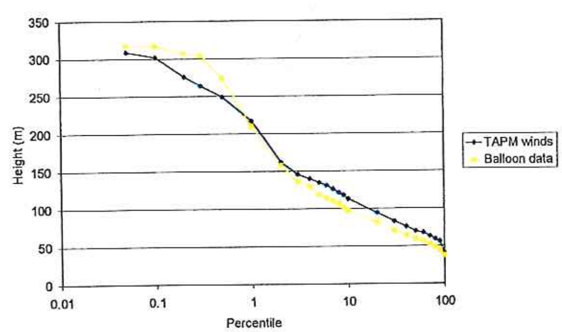

Figure 3: Comparison of Spillane plume height calculations for TAPM - generated and measured winds.

7. Design options

Decreasing the exit velocity will reduce the initial flow development length but plume buoyancy is the key factor in the magnitude of the vertical velocity. Similarly any reduction in stack height gives little benefit to aviation safety concerns and may risk poor plume dispersion in high-wind conditions (due to building wake influences). Increasing the stack separation does delay the time when plumes merge but with little overall practical benefit (Figure 4). Horizontally-pointing stack exits will reduce initial momentum but again buoyancy is dominant.

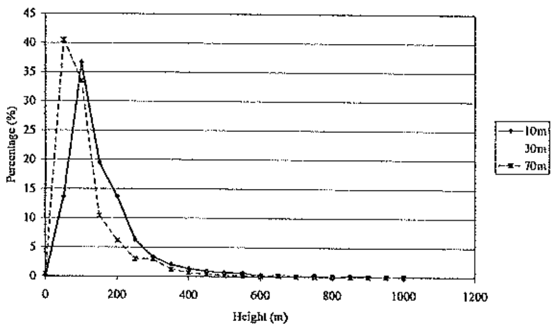

Figure 4: Frequency of critical height for varying stack configurations.

The reduction of plume buoyancy by using heat recovery results in a very significant reduction of critical heights but open-cycle operation usually has to be considered in any risk assessment. For critical cases, it appears better to take advantage of the relatively small zone of influence on vertical velocities and the usual requirement of CASA to identify stack locations for low-flying aircraft. A notice to aircrew together with real-time indication of site operations may be effective in most situations.

8. Conclusions

Methodologies now exist for major point sources and point to the dominating role of initial plume buoyancy. Detailed measurements are required for light-wind conditions and are readily taken by experienced research aircrews. TAPM methodologies are reasonable for single plumes but inappropriate for multiple plumes. For key sites, remote sensing equipment is required to gather reliable wind statistics in the critical 100-500 m range. Theoretical advances are needed to treat inversion penetration in very light-wind conditions and to extend the methods to moist plumes and different source geometries.
